What is This?
Matchmaking Promotes Happiness

Lalin Anik1 and Michael I. Norton2

Abstract
Four studies document and explore the psychology underlying people’s proclivity to connect people to each other—to play “matchmaker.” First, Study 1 shows that chronic matchmaking is associated with higher well-being. Studies 2 and 3 show that matching others on how well they will get along increases happiness and is more intrinsically rewarding than other tasks (e.g., deciding which people would not get along). Study 4 investigates a moderator of the rewarding nature of matchmaking: the type of connection. We show that bridging ties are relatively more attractive than bonding ties: The more unlikely the match, the more rewarding it is. Taken together, these studies provide correlational and causal evidence for the role of matchmaking in promoting happiness.

Keywords
matchmaking, social capital, happiness, social networks, tie strength

At some point, most people have made matches between others, from introducing strangers at a party to brokering romantic connections. Indeed, social networking websites such as Facebook and LinkedIn increasingly make brokering such introductions as effortless as a few clicks of a mouse. In fact, people often err on the side of “overintroduction,” checking to make sure that two people know each other only to find that the two are already acquainted. Despite its ubiquity, the psychological drivers of such matchmaking have received little attention, with some perspectives suggesting that matchmaking has negative costs to the matchmaker. We investigate the proclivity to make matches between others, demonstrating that such matchmaking is both intrinsically rewarding and pays in the form of increased well-being.

A great deal of evidence suggests that people enjoy connecting themselves to others and that such connections are associated with well-being. Humans spend some 80% of their waking hours in the company of others (Emler, 1994; Kahne, 2004), checking to make sure that two people know each other only to find that the two are already acquainted. Despite its ubiquity, the psychological drivers of such matchmaking have received little attention, with some perspectives suggesting that matchmaking has negative costs to the matchmaker. We investigate the proclivity to make matches between others, demonstrating that such matchmaking is both intrinsically rewarding and pays in the form of increased well-being.

Why might people find matchmaking rewarding? Existing research suggests that the benefits of matchmaking may arise due to a variety of motivations. Introducing unacquainted individuals may allow matchmakers to signal positive traits such as social acumen and intelligence to themselves (Bem, 1972; Bodner & Prelec, 2003). But people also engage in public displays—such as conspicuous consumption—to signal their status and power to others (Bekker, 1974; Glazer & Konrad, 1996; Griskevicius et al., 2007); being the person who brings others together may signal one’s status in the social network.

Matchmaking and Happiness
The previous research clearly demonstrates the positive impact of having connections, but the possibility that initiating connections for others might also impact well-being remains unexplored. In short, we explore the emotional benefits of making matches between two other people. We note that matchmaking takes many forms, from romantic matchmaking (e.g., connecting partners for dates) to social matchmaking (e.g., introducing friends and acquaintances) to professional matchmaking (e.g., linking two colleagues). Though the term “matchmaking” is most commonly associated with romantic efforts, we use the term to refer to a broad category of connections to explore the general emotional benefits of matchmaking.

Why might people find matchmaking rewarding? Existing research suggests that the benefits of matchmaking may arise due to a variety of motivations. Introducing unacquainted individuals may allow matchmakers to signal positive traits such as social acumen and intelligence to themselves (Bem, 1972; Bodner & Prelec, 2003). Indeed, connecting two people who form a lasting partnership—whether romantic, platonic, or professional—may put those individuals in the matchmakers’ debt, leading them to reciprocate in the future (Cialdini, 1993). Relatedly, matchmaking may signal that the matchmaker is a helpful person, which may increase others’ likelihood of behaving generously to the matchmaker; indeed, matchmaking increases the density of social networks, which has been shown to facilitate trust and cooperation (Coleman, 1990; Ibarra, 1992). Matchmakers might also have altruistic motivations: to increase the happiness and well-being of others. The act of connecting two lonely people, for example, might be driven by a desire to increase their happiness; altruistic behaviors have been shown to have emotional benefits for both givers and receivers (Dunn, Aknin, & Norton, 2008). Given the variety of research supporting a possible link between matchmaking and well-being, we suggest that matchmaking may promote happiness.

Overview

We first explore whether chronic matchmakers—those who habitually connect others in their everyday lives—have higher well-being (Study 1). Next, we measure the benefits of matchmaking in two ways, by assessing happiness before and after engaging in matchmaking (Study 2) and examining intrinsic willingness to persist at creating connections between others (Study 3). We pit the rewarding nature of matchmaking against another kind of reward—money—and explore whether paying people to make matches between others “crowds out” their inherent desire to create connections (Study 3). Finally, Study 4 investigates a moderator of the rewarding nature of matchmaking: the type of connection.

Study 1: Matchmaking Correlates With Well-Being

Study 1 offers an initial examination of the relationship between chronic matchmaking and overall well-being. In addition, because chronic matchmakers may have larger social networks, in and of itself a predictor of well-being (Burt, 1987; Chan & Lee, 2006), we control for network size. Since matchmakers may have personality traits (e.g., extraversion) that correlate with well-being (DeNeve & Cooper, 1998), we also control for personality traits. In an online survey, participants rated their propensity to make matches between others and their perceived success at matchmaking, reported their total number of acquaintances and friends, and completed well-validated scales assessing subjective well-being and personality.

Method

A sample of 301 participants (32% female; $M_{age} = 29.1$, standard deviation $[SD] = 9.2$) were recruited on Amazon’s Mechanical Turk for a 5-min study on social interactions and were paid US$.25. Respondents rated their propensity to make matches between others and their perceived success at matchmaking. We used 4 items to assess people’s propensity to make matches between others: I introduce my acquaintances to each other, I introduce my friends to each other, I set up my friends on dates, and I am a resource for people around me to find social and professional connections (Cronbach’s $\alpha = .81$). These items were rated on a 4-point scale ($1 = not at all true of me to 4 = very true of me$). We used 4 items to assess their perceived success at making connections: How good are you at connecting your friends with each other? How good are you at connecting your acquaintances with each other? How good are you at setting up your friends on dates? and What percentage of these dates are successful? (Cronbach’s $\alpha = .85$). The first 3 items were rated on a 10-point scale ($1 = not at all good at it to 10 = extremely good at it$), and participants provided open-ended responses to the percentage question; we standardized these items to create the composite measure.

Respondents also reported their total number of acquaintances and total number of friends, and completed Diener, Emmons, Larsen, and Griffin’s (1985) well-being scale (Cronbach’s $\alpha = .85$). Finally, participants completed the Ten-Item Personality Inventory (Gosling, Rentfrow, & Swann, 2003), which measures the Big Five personality dimensions (extraversion, agreeableness, conscientiousness, emotional stability, and openness to experiences) on a 7-point scale ($1 = disagree strongly to 7 = agree strongly$).

Results

Both propensity to make matches and perceived success at matchmaking were positively correlated with well-being, $r_{s} = .36$ and $.37, ps < .001$. Interestingly, the 7 individual items for each scale (4 for propensity, 3 for perceived success) displayed striking consistency in their correlation with well-being, $.24 < r_{s} < .35, all ps < .001$. Thus, despite the different types of matchmaking assessed—from setting up friends on dates ($r = .28$) to introducing friends to each other ($r = .31$)—matchmaking appears to have a consistent positive relationship with well-being.

Number of acquaintances and number of friends were each correlated with propensity, $r_{s} = .13$ and $.12, ps < .04$, and perceived success, $r_{s} = .15$ and $.14, ps < .02$. However, when we controlled for number of friends and acquaintances, the relationships between well-being and both propensity and perceived success remained significant, $\beta_{s} = .36$ and $.37, ps < .001$. Moreover, when we controlled for the five personality dimensions, the relationships between well-being and both propensity and perceived success also remained significant, $\beta_{s} = .25$ and $.24, ps < .001$. In the regressions for both propensity and perceived success, emotional stability predicted well-being, $ps < .001$; extraversion was a significant predictor in the former analysis, $p < .05$, and marginally significant in the latter, $p = .055$; no other factors emerged as significant predictors in either analysis, $ps > .07$. 

Downloaded from ssp.sagepub.com by guest on July 1, 2014
While we replicated previous findings that extraversion and emotional stability are both positively related to well-being, we demonstrate a significant relationship between propensity to make matches and perceived success at matchmaking when controlling for the size of participants’ network and other personality variables. These results provide preliminary correlational evidence that chronic matchmakers are happier with their lives, over and above any effect of the size of their networks or their personality traits.

Study 2: Matchmaking in the Laboratory

In Study 2, we tested the causal impact of matchmaking on happiness in a laboratory setting by assigning people to match individuals to each other and measuring their happiness before and after the matching task. In addition, we investigated whether the type of match matters by randomly assigning people to one of the three tasks: making matches on the basis of who would get along well (the match condition), who would get along poorly (mismatch), and who had the most similar last four digits of their social security numbers (random). We included the random condition to examine whether matchmaking based on any similarity would increase happiness or whether the emotional benefits of matchmaking are specific to meaningful connections. We included both the match and mismatch conditions because each required participants to think about social relationships between others, which may have been interesting in its own right. We expected, however, that matching people with the goal of creating connections (match) would lead to greater happiness than matching on other dimensions (mismatch or random).

Method

Participants (N = 118; 61% female, M_age = 22.5, SD = 4.4) were recruited from the subject pool of a university in the northeastern United States for a study about “the sharing of daily experience” that paid US$12. Participants completed the study in groups of six; two participants did not show such that our final sample consisted of 18 groups of six and 2 groups of five participants.

Participants first reported their happiness by marking a 17-cm line with ends points not at all happy and very happy (Morewedge, Gilbert, Keysar, Berkovits, & Wilson, 2007). Next, participants introduced themselves to each other by stating their name, place of birth, occupation, and hobbies; we included this “warm-up” task to give them some basis for making matches. After completing the “warm-up” task, participants were informed that they would be making matches between others in the room, and each group was randomly assigned to one of the three tasks. In the match condition, participants were asked to match pairs of people whom they thought would get along well; those in the mismatch condition were asked to match pairs whom they thought would not get along well; those in the random condition were asked to match pairs whom they thought had the most similar last two digits of their social security numbers. In order to increase involvement in the matching task, participants were informed that the pairs they selected would interact in the next part of the study.

Next, participants again completed the same happiness measure. Based on the matches made, three pairs were selected to move to a separate room for a 5-min interaction in which participants told each other more about themselves.

Results

Participants were nested in groups which were in turn nested within the three conditions. Therefore, we conducted a 3 (condition: match, mismatch, and random) × 2 (time of measurement: pretask and posttask) mixed-effects model with random factors for participants, groups, and the groups by time of measurement interaction, which revealed the predicted significant interaction between condition and time of measurement, F(2, 115) = 6.22, p = .003, η²_p = .10. As our account suggests, contrasts revealed that participants in the match condition experienced a significant increase in prematching happiness (M = 11.16, SD = 2.29), t(115) = 3.10, p = .003. If anything, happiness declined in both the mismatch (M = 10.97 and 10.53, SDs = 3.34 and 3.29) and random conditions (M = 11.86 and 11.60, SDs = 2.73 and 2.46), although these differences were not significant, ps > .11. Further contrasts showed that the boost in happiness in the match condition was significantly greater than the decrease in happiness in both the mismatch and random conditions, ps < .004.

In sum, Study 2 offers initial evidence that assigning people to matchmaking increases their happiness—but only when that matching is done in the service of creating connections between others.

Study 3: Matchmaking is Intrinsically Rewarding

In Study 3, we assessed the benefits of matchmaking using a different methodology: We measured the intrinsic reward of matchmaking by examining people’s persistence on one of the two tasks: matching which of the three people a target individual would rather get along with best (match) or looks most like (appearance).

We also varied whether participants completed each trial of the task for free, for 1¢, or for 2¢, a design that allowed us to document the intrinsic reward of matchmaking in two ways. First, we expected that participants would be willing to complete more trials of the match task than the appearance, providing evidence for greater intrinsic reward of the former task. Second, while we expected that higher pay per trial would increase the number of trials that participants completed of the less intrinsically rewarding appearance task, we explored whether paying participants for the intrinsically rewarding match task might actually undermine their motivation and lead them to complete fewer trials. Research shows that providing extrinsic rewards—such as monetary incentives—for completing intrinsically satisfying tasks are not only ineffective but can
be detrimental, “crowding out” people’s motivation to perform those tasks (Deci, 1975; Lepper, Greene, & Nisbett, 1973). As a result, we predicted that providing extrinsic monetary rewards for the intrinsically rewarding match task would diminish participants’ motivation to complete this task.

**Method**

Participants \((N = 168, 54\% \text{ female}, M_{\text{age}} = 21.6, SD = 3.8)\) were recruited from the subject pool of a university in the northeastern United States for a 60-min session that involved completing a series of unrelated studies that paid US$15. Participants were informed that they would be completing 50 trials of computer tasks and could choose how to split these 50 trials between two tasks. In the first task, participants were shown a photo of a target individual and asked to match the target with one of the three potential matches (see Figure 1 for an example of the task). Participants were randomly assigned to one cell of a 2 (condition: match, appearance) \(\times\) 3 (incentives: free, 1¢, 2¢) design. Participants either selected the person with whom the target would get along best (match) or the person who was most physically similar to the target (appearance); in addition, they either completed the task without incentives (free), or for either 1¢ or 2¢ for each trial. After each trial, they were given the choice to complete another trial of this task or switch to work on a second (letter) task, which consisted of finding a target letter in a pull-down menu of four letters.

Participants were told they would begin with the first task (match or appearance) and could complete all 50 trials of that task or move on to the letter task—designed to be boring—whenever they wished. After completing a practice trial of each task, they began with either match or appearance task. Our dependent variable was the number of trials completed before switching to the letter task.

**Results**

**Pretest**

We pretested task enjoyment with a separate group of participants \((N = 103, 58.4\% \text{ female}, M_{\text{age}} = 34.4, SD = 11.8)\) who completed one trial of each task (match, appearance, letter) and rated them on enjoyment on a 7-point scale \((1 = \text{not at all to } 7 = \text{very much})\). Ratings of the matching task \((M = 4.21, SD = 1.70)\) and appearance task \((M = 4.25, SD = 1.64)\) did not differ, \(F(1, 102) = .05, p = .83\); as expected, both received...
higher ratings than the letter task \((M = 2.42, SD = 1.69)\), \(Fs > 80.00, ps < .001\).

Number of Trials

A 2 (condition: match, appearance) \(\times\) 3 (incentives: free, 1\(\epsilon\), 2\(\epsilon\)) analysis of variance (ANOVA) revealed no main effect of condition, \(F(1, 161) = 2.50, p = .12\), or incentives, \(F(2, 161) = .86, p = .47\), but did reveal the predicted interaction, \(F(2, 161) = 5.11, p < .01, \eta^2_p = .10\) (Figure 2). First, as expected, participants in the free conditions completed more than twice as many trials of the match task \((M = 31.10, SD = 20.25)\) than the appearance task \((M = 14.82, SD = 15.34)\), \(t(57) = 3.45, p < .001, d = .90\), suggesting that connecting others in terms of liking is intrinsically more rewarding than connecting others for physical similarity.

Our second means of demonstrating intrinsic liking for the match task was to examine how additional monetary incentives would differentially impact people’s desire to complete additional trials of both the appearance and match task. As expected, incentives increased the number of trials participants chose to complete the appearance task in a significant linear trend from free to 1\(\epsilon\) to 2\(\epsilon\) \((Ms = 14.82, 17.07, \text{and } 26.27, SDs = 15.33, 17.49, \text{and } 21.45), t(82) = 2.37, p = .02\). In contrast, providing incentives for the match task resulted in a significantly decreased willingness to complete trials both for participants in the 1\(\epsilon\) and 2\(\epsilon\) conditions \((Ms = 20.25 \text{ and } 20.18, SDs = 18.53 \text{ and } 19.40)\) compared to those in the free condition \((M = 31.10, SD = 20.24)\), \(ts > 2.04, ps < .05\) (Figure 2). These results suggest that while payment increased motivation for the less intrinsically appealing appearance task, incentives crowded out motivation for the more intrinsically appealing match task—such that paying more led to completing fewer trials.

Indeed, one final piece of evidence speaks to the inherently rewarding nature of the match task: We needed to pay 2\(\epsilon\) per trial for the appearance task in order to induce people to complete even close to as many trials as they were willing to complete of the match task for free.

One possible explanation for our results is that happiness is due to having completed a task successfully. We conducted an additional study in which we both controlled for successful completion of the task and measured subjective feelings of success. Participants \((N = 121, 58\% \text{ female, } M_{age} = 33.6, SD = 11.7)\) completed a similar computer paradigm as in Study 3, with two changes. In order to control for the successful completion of the task, all participants were assigned to complete 10 trials in one of the three conditions: matching which of the three people a target individual would either get along with best (match) or least (mismatch), or which the target resembled most (appearance). Participants rated their happiness before and after the task on a 7-point scale (1 = very unhappy to 7 = very happy) as well as how successful they thought they were at making these matches on a 7-point scale (1 = very unsuccessful to 7 = very successful). A 3 (condition: match, mismatch, and appearance) \(\times\) 2 (time of measurement: pretask and posttask) ANOVA revealed the predicted interaction between condition and time, \(F(2, 118) = 5.83, p = .004, \eta^2_p = .09\). Replicating our previous results, participants in the match condition experienced a significant increase from prematching \((M = 5.19, SD = 1.18)\) to postmatching happiness \((M = 5.36, SD = 1.11), t(42) = 2.47, p = .02\). Happiness declined in both the mismatch \((Ms = 5.02 \text{ and } 4.76, SDs = .95 \text{ and } 1.26)\) and appearance conditions \((Ms = 5.36 \text{ and } 5.08, SDs = 1.07 \text{ and } 1.05)\), and these differences were significant, \(ps < .04\). However, a one-way ANOVA revealed no differences between participants’ perceived success at different tasks, \(F(2, 118) = 1.91, p = .15\). These results suggest that matchmaking itself—and not merely the successful completion of tasks—is uniquely rewarding.

Study 4: What Kinds of Matches Are Most Rewarding?

In Study 4, we explored a moderating factor of the impact of matchmaking on happiness: the type of connection. We posited that one reason that people find matchmaking rewarding is because it creates novel connections that increase network density. If this is the case, then creating matches between people who are unlikely to know each other should prove more rewarding than creating matches between people who are likely to know each other, because the former matches have more potential to increase network density (Gittell & Vidal, 1998). Bridging ties, which connect people who previously did not know each other, offer rare and novel opportunities for creating social capital at the level of the group; bonding ties, on the other hand, offer fewer benefits to the group as they primarily connect people who already have ties in common. We operationalized bridging and bonding ties by varying the gender and race of the people being matched; research suggests that similar people are more likely to interact than dissimilar people, such that creating a connection between members of different groups (e.g., a White male with an Asian female) is more likely...
to be a bridging tie than a connection made between members of the same group (e.g., two White males; McPherson, Smith-Lovin, & Cook, 2001).

Using several versions of the match task, we explored whether creating bridging ties would be more rewarding than creating bonding ties.

**Method**

Participants ($N = 132$, 49% female, $M_{age} = 21.1$, $SD = 3.6$) were recruited from the subject pool of a university in the northeastern United States for a 90-min session that involved completing a series of unrelated studies that paid US$20.

As in Study 3, participants completed 50 trials of two tasks: the matching task or boring letter task; also as in Study 3, they could choose to complete as many trials of each task as they chose. All participants were randomly assigned to one of the eight versions of the match task from the previous study. In each version, the target individual was always either a Caucasian male or a Caucasian female; to manipulate the likelihood that the target individual would know the two possible matches, we varied the gender and race of the two matches—Caucasian males, Caucasian females, Asian males, or Asian females. We collapsed these eight versions into three levels of ties—same-race and same-gender versions (bonding ties), different gender and different race versions (bridging ties), or same-race and different gender or different gender and same-race versions (medium ties; see Figure 3 for examples of ties).

**Results**

**Pretest**

We pretested these combinations to ensure that they successfully manipulated tie level. In a within-subjects design, a separate group of participants ($N = 116$, 47% female, $M_{age} = 29.2$, $SD = 9.1$) were shown 50 trials including examples from the eight different versions. They rated the likelihood that the target person would know one of the two people below on a 7-point scale (1 = extremely unlikely to 7 = extremely likely). Bonding ties were rated as having a higher likelihood of knowing each other ($M = 4.78$, $SD = .94$) than both medium ties ($M = 4.07$, $SD = .86$) and bridging ties ($M = 3.52$, $SD = .95$), $F(2, 931) = 118.69$, $p < .001$; all three ratings were significantly different from each other, all $t$s > 7.68, all $p$s < .001.

**Number of Trials**

Type of tie impacted the number of matching trials completed, $F(2, 128) = 2.85$, $p < .05$. The linear trend was significant, $t(129) = 2.92$, $p < .01$, such that participants completed the greatest number of trials when matching across bridging ties ($M = 25.03$, $SD = 18.22$) followed by medium ties ($M = 19.64$, $SD = 15.73$) followed by bonding ties ($M = 13.28$, $SD = 13.98$); indeed, participants in the bridging ties condition completed nearly twice as many trials as those in the bonding ties condition, $t(61) = 2.88$, $p < .01$.

By definition, bridging ties involved matching people of the same gender, whereas bonding ties involved matching people of different genders. If participants made the assumption that the target individuals were heterosexual, it is possible that bonding ties were more rewarding than bridging ties because they involved romantic matchmaking. However, an examination of the different types of medium ties suggests that opposite-gender pairings do not differ from same-gender pairings: Caucasian female with Caucasian males ($M = 18.18$), Caucasian female with Asian females ($M = 19.25$), Caucasian male with Asian males ($M = 19.44$), and Caucasian male with Caucasian females ($M = 21.88$), $t$s < .70, $p$s > .49. As in Study 1—in which making romantic and platonic connections were similarly correlated with well-being—these results offer evidence for the benefits of many types of matchmaking.

![Figure 3](image-url) Figure 3. Example bonding tie: Caucasian female target with Caucasian female potential matches (A); Example medium tie: Caucasian female target with Asian female potential matches (B); Example bridging tie: Caucasian female target with Asian male potential matches (C; Study 4).
General Discussion
Taken together, these studies provided evidence for our proposed link between matchmaking and happiness. Inducing people to make matches between strangers increased happiness in the moment, and people found a task that involved matching others based on their beliefs about their likely rapport to be more intrinsically rewarding than tasks that involved other types of matching. We documented a critical moderator of rewarding nature of matchmaking: Creating bridging ties—connecting people who would not otherwise be acquainted—is more rewarding than bonding ties.

Our laboratory studies are, of course, proxies for real-world matchmaking. The fact that this kind of minimalistic matchmaking continues to provide rewards parallels other research suggesting that minimalistic laboratory paradigms—for example, simulating gossip and altruistic punishment (Fehr & Gächter, 2002; Feinberg, Willer, Stellar, & Keltner, 2012)—can prove fruitful in understanding emotional consequences of behavior. Importantly, our results in Study 1 further support that matchmaking proves rewarding beyond the laboratory setting. At the same time, investigations that extend our results into everyday settings will offer further insight into the psychology of matchmaking. For example, a daily diary methodology could be used to examine whether people are happier on days when they connect others, while online social networks such as Facebook and LinkedIn offer readily available opportunities to assess both platonic and professional matchmaking.

Our results offer several directions for future research. First, it would be worthwhile to examine whether matchmaking is driven by altruistic or selfish reasons—or a combination of two. Are matchmakers still happy if they make an introduction between two others who leave and interact without them? Relatedly, assessing people’s preference for public versus anonymous matches would test whether social signaling is a driver of matchmaking: People preferring to be recognized for their matches—by the matched pair or observers—would offer evidence that matchmaking is not driven by purely altruistic motivations.

Our results stand in seeming contrast to social network research suggesting that matchmaking can come with costs. Burt (2001) posits that social networks are like a market in which some people achieve more prominent places but the benefits they derive depend on the type of network. Networks with structural holes (where there are missing links between network members) allow some individuals to have more access to resources than others (Coleman, 1990). These brokers, strategically located between others, derive power from refusing to connect others in order to maintain their standing; in this view, matchmaking could have a negative impact as it would come with the cost of the matchmaker’s structural advantage (Burt, 1998; Simmel, 1955). Our studies show that closing gaps in social networks have benefits for the matchmaker in the form of increased happiness. Future research can pit the positive benefits of matchmaking against the benefits of being a broker in a network to examine whether people would engage in matchmaking even when it is costly to do so.

We document a novel means by which people can increase their happiness: As with other behaviors such as spending money on others (Dunn et al., 2008) and performing random acts of kindness (Lyubomirsky, Sheldon, & Schkade, 2005), successful matchmaking promotes happiness in matchmakers. Also, matchmaking is similarly easy to implement: Unlike other behaviors that increase happiness, such as exercise and becoming more religious (Mochon, Norton, & Ariely, 2008), matchmaking doesn’t require a great deal of time and effort. Moreover, creating successful matches between others can have additional benefits that extend beyond the matchmaker to the two newly acquainted individuals, from providing them with opportunities for employment (Granovetter, 1973) to increasing their social support. Even more broadly, matchmaking increases the density of social networks—more people know more people in common—and this kind of social capital is associated with a range of positive group-level outcomes including lower crime rates and improved public health (Putnam, 2001). As a result, the benefits of matchmaking may extend beyond the matchmakers to the matched dyads and to the wider community.

Notes
1. A 3 (condition: match, mismatch, and random) × 2 (happiness: pretask and posttask) × 2 (gender: male or female) analysis of variance (ANOVA) revealed no main effect of gender or interactions with gender, all Fs < .72, all ps > .49. Similarly, including gender does not substantially change our results in Studies 2–4; we therefore do not report this variable further.
2. The results for the different forms that each type of tie took were similar. Bonding ties: Caucasian female with Caucasian females (Mean = 14.72, SD = 16.05) and Caucasian male with Caucasian males (Mean = 11.43, SD = 11.08); Medium ties: Caucasian female with Asian females (Mean = 19.25, SD = 17.40), Caucasian female with Caucasian males (Mean = 18.18, SD = 14.45), Caucasian male with Asian males (Mean = 19.44, SD = 15.73), and Caucasian male with Caucasian females (Mean = 21.88, SD = 16.14); Bridging ties: Caucasian female with Asian males (Mean = 25.41, SD = 18.40) and Caucasian male with Asian females (Mean = 24.57, SD = 18.69).
