October 12, 2011

## Abstract

We propose a scalable, data-driven method for designing national policies for the allocation of deceased donor kidneys to patients on a waiting list, in a fair and efficient way. We focus on policies that have the same form as the one currently used in the U.S. In particular, we consider policies that are based on a point system, which ranks patients according to some priority criteria, *e.g.*, waiting time, medical urgency, etc., or a combination thereof. Rather than making specific assumptions about fairness principles or priority criteria, our method offers the designer the flexibility to select his desired criteria and fairness constraints from a broad class of allowable constraints. The method then designs a point system that is based on the selected priority criteria, and approximately maximizes medical efficiency, *i.e.*, life year gains from transplant, while simultaneously enforcing selected fairness constraints.

Among the several case studies we present employing our method, one case study designs a point system that has the same form, uses the same criteria and satisfies the same fairness constraints as the point system that was recently proposed by U.S. policymakers. In addition, the point system we design delivers an 8% increase in extra life year gains. We evaluate the performance of all policies under consideration using the same statistical and simulation tools and data as the U.S. policymakers use. Other case studies perform a sensitivity analysis (for instance, demonstrating that the increase in extra life year gains by relaxing certain fairness constraints can be as high as 30%), and also pursue the design of policies targeted specifically at remedying criticisms leveled at the recent point system proposed by U.S. policymakers.

# 1. Introduction

Renal or kidney transplantation and maintenance dialysis are the only treatments for *end-stage renal disease* (ESRD), a terminal disease affecting over 500,000 people currently in the United States, see USRDS (2009). Despite being a major surgical procedure, transplantation is the treatment of choice for ESRD patients, as a successful transplantation improves their quality of life. In particular, dialysis treatment requires that the patient visits a dialysis center for at least 12 hours each week, whereas transplantation typically allows the patient to resume regular life activities. Furthermore, a multitude of research and clinical studies have statistically demonstrated that transplantation also reduces the mortality risk for patients, see Suthanthiran and Strom (1994), Schnuelle et al. (1998), Port et al. (1993), Ojo et al. (1994). Thus, a kidney transplant is considered by many as a potentially life-saving gift.

The two sources of kidneys for transplantation are living donors (*e.g.*, family members or friends of the patient) and deceased or cadaveric donors. The majority of patients are unsuccessful in finding living donors, and thus join a pool of patients waiting for a deceased donor organ. Of course, while in the living donor case the donation is typically made to a specific patient, in the deceased donor case an important allocation problem arises. In particular, once an organ is procured from a deceased donor, there can be thousands of medically compatible and available recipients the organ can be allocated to. The problem becomes even more significant, if one accounts for the organ shortage and the size of the pool of waiting patients in the United States: On October 20th 2010, 86,391 patients were waiting for a kidney transplant. In 2009, there were 33,671 new additions, but only 16,829 transplantations were performed, from which 10,442 transplants were from deceased donors. For more information and statistical details we refer the reader to UNOS (2010).

In recognition of the aforementioned allocation problem and the growing difficulty of matching supply and demand, the U.S. Congress passed the *National Organ Transplant Act* (NOTA) in 1984. According to this legislation, deceased donor organs are viewed as national resources in the U.S., and as such, their allocation has to be based on fair and equitable policies. Moreover, the sale of organs as well as money transfers of any nature in the acquisition of organs are strictly prohibited. Instead, the policy for allocating the organs should utilize waiting lists and have the form of a *priority method*. That means that patients in need of a transplant register on waiting lists. Then,

once an organ is procured, all medically compatible patients are ranked according to some priority rules and the organ is successively offered to them according to their ranking, until it is accepted by a patient. Subsequent to the NOTA, the U.S. Congress established in 1984 the *Organ Procurement and Transplantation Network* (OPTN) in order for it to maintain a national registry for organ matching and develop allocation policies.

Naturally, the aforementioned allocation policies are of central importance and have to accomplish major objectives in alleviating human suffering, prolonging life and providing nondiscriminatory, fair and equal access to organs for all patients, independent of their race, age, blood group or other peculiar physiological characteristics. Some of the main challenges in designing a kidney allocation policy are the following:

- *Fairness constraints:* What does fair and equal access to organs mean? Due to the subjective nature of fairness, there is no single fairness criterion that is universally accepted by policymakers and academics alike. As such, a great challenge lies in identifying the appropriate fairness constraints that the allocation outcomes of a policy should ideally satisfy. An example of such a constraint could be a lower bound on the percentage of organs allocated to a particular group of patients – say, requiring that at least 47% of all transplants are received by recipients of blood type O. In the absence of such a constraint these groups would otherwise be handicapped and not have access to organs because of their physiological characteristics. A number of such criteria have been studied by OPTN policymakers (see OPTNKTC (2008), RFI (2008)).
- *Efficiency:* As a successful transplantation typically prolongs the life of a patient, while also improving his quality of life, the policy needs to ensure that the number of quality adjusted life year gains garnered by transplantation activities is as high as possible. This is also in line with the view of organs as national resources. Again, this objective is of paramount importance to the current policy design, see OPTNKTC (2008).
- *Prioritization criteria:* The policy needs to be based on medically justified criteria and physiological characteristics of patients and organs in order to rank patients. However, ethical rules disallow the use of criteria that can be deemed as discriminatory (*e.g.*, race, gender, etc.).

- *Simplicity*: Patients need to make important decisions about their treatment options, together with their physicians. To this end, they need to be able to estimate the probability of receiving an organ, or at least understand the allocation mechanism. For that reason, the priority method that is used needs to be simple and easy to communicate.
- *Implementation*: Suppose that one has selected the desired fairness constraints, prioritization criteria and a simple priority method. How does he then balance the emphasis put on the different prioritization criteria, so as to design a policy whose allocation outcomes would maximize efficiency, while satisfying the fairness constraints?

All the above challenges were faced by the OPTN policymakers in 2004, when they initiated the development of a new national allocation policy that will eventually replace the current one. In 2008, the OPTN released a concrete proposal in a *Request for Information* publication (RFI (2008)) that is currently under consideration by the U.S. Department of Health and Human Services.

In this work, we deal with the implementation challenge in designing a national allocation policy, while accounting for all the other challenges above. In particular, we focus on perhaps the simplest, most common and currently in use priority method, namely a point system. We make the following contributions:

1. We present a novel method for designing allocation policies based on point systems in a systematic, data-driven way. Our method offers the flexibility to the policymaker to select the fairness constraints he desires, as well as the prioritization criteria on which the point system will be based on. The method then outputs a conforming point system policy that approximately maximizes medical efficiency, while satisfying the fairness constraints.
2. To validate our proposed method, we utilize it to design policies under different scenarios of interest to OPTN policymakers. Under a particular scenario, we design a policy that (a) matches the fairness constraints of the recently proposed policy by U.S. policymakers, and (b) is based on the same criteria and simple scoring rule format. Critically though, it achieves an 8% increase in anticipated extra life year gains, as demonstrated by our numerical simulations, which are based on the statistical and simulation tools currently in use by U.S. policymakers (see below).

3. We use our method to perform a sensitivity analysis that explores the consequences from relaxing or introducing fairness constraints – for instance, what is the impact of reducing the percentage of transplants to patients on dialysis for greater than 15 years by 1%? In the case of some constraints, relaxations of fairness constraints can result in life year gains on the order of 30%. As such, we believe this is a valuable tool in the policy design process.
4. This paper makes a methodological contribution to the area of Approximate Dynamic Programming. In particular, we develop a means of designing approximately optimal policies in problems of dynamic allocation that are *massively* high dimensional. In particular, these are allocation problems where the number of “classes” of objects being allocated, and the number of “bins” these objects may be allocated to are themselves intractably large. A previous approach to this issue has simply been “clustering” these classes so as to arrive at a problem with, say, tens of classes of objects. This approach is a non-starter in the context of designing real (as opposed to stylized) policies for organ allocation, and we provide a viable alternative that requires no clustering whatsoever.

Performance in all our numerical studies is evaluated using the same statistical and simulation tools, as well as data, as the U.S. policymakers use. Those tools and datasets were obtained directly from their developers, namely the *United Network for Organ Sharing* (UNOS), which is the non-profit organization that operates the OPTN, and the *Scientific Registry of Transplant Recipients* (SRTR).

The structure of this paper is as follows. In the next subsection, we review relevant work in the literature. Section 2 provides background information on the distribution of organs, the current allocation policy, as well as updates on the recent development of a new proposed policy. In Section 3, we discuss our method for designing allocation policies in detail. Section 4 includes numerical evidence of the usefulness of our work through the design of new policies under multiple case studies, including a sensitivity analysis, and the evaluation of their performance via simulation. We conclude in Section 5 with an overview of future prospects for the approach delineated in this paper. A list of acronyms used appears at the end of this paper.

## 1.1. Literature Review

The model-based analysis of the organ allocation process has attracted significant interest in the academic literature. One of the first papers in this vein is by Ruth et al. (1985), in which the

authors develop a simulation model to study the problem. Shechter et al. (2005) also introduce a discrete event simulation model for the evaluation of potential changes to the liver allocation process. In this work, we utilize the simulation model developed by the SRTR, see KPSAM (2008).

The organ allocation process was also analyzed by Richter (1989) and David and Yechiali (1995) via a stochastic assignment problem formulation. In their work, they analyze stylized models that fit into that framework. In this work, we also utilize an assignment problem formulation, but only for the training phase of our methodology: the output allocation policies of our framework are rather simple, based on scoring rules and in full compliance with policies that U.S. policymakers consider, unlike the above referenced work. In a similar vein, Zenios et al. (2000) introduce a fluid model approximation of the organ allocation process that allows them to explicitly account for fairness and medical efficiency in the allocation. Our framework accounts for fairness in accordance with the considerations of policymakers. Zenios (2002), Roth et al. (2004), Segev et al. (2005) and Ashlagi et al. (2011) study the problem of living donation and the allocation of kidneys. Kong et al. (2010), Sandikci et al. (2008) and Akan et al. (2011) also tackle the problem of liver allocation.

Another stream of research focuses on the decision-making behavior of patients, by dealing with organ acceptance policies. David and Yechiali (1985) model the candidate's problem as an optimal stopping problem. Similar acceptance policies are developed by Ahn and Hornberger (1996), Howard (2002), Alagoz (2004) and Alagoz et al. (2007). The present paper will test policies on a simulator developed by SRTR for OPTN; this simulator assumes a specific, exogenous acceptance model for patients built from historical data. While the acceptance model ignores endogeneity, it allows us to simulate outcomes in precisely the manner policy makers currently do.

Recent work by Su and Zenios (2005, 2004) attempts to combine the above streams of research by explicitly accounting for the acceptance behavior of patients in the development of an allocation policy. In a similar vein, Su and Zenios (2006) propose an allocation mechanism that elicits the utilities of the patients. For more details, we refer the reader to the thorough review by Zenios (2005).

In all the above referenced work dealing with organ allocation policies, the authors design general near optimal dynamic policies. These papers take the important perspective of designing a *fundamentally new* allocation system from the ground up. In our work, we restrict our attention to policies that comply with the precise constraints imposed by current practice. That is, we focus

our attention on policies based on simple point systems of the precise format as the ones currently in use and proposed by U.S. policymakers. Moreover, instead of designing a particular policy, we develop a framework that admits various fairness constraints and prioritization criteria. In other words, we design a mechanism that can fit directly in the *current* decision-making process of the U.S. policymakers.

## 2. Distribution and Allocation Policies

In this section, we briefly review the distribution process and the operation of the UNOS/OPTN as coordinators and developers of national policies for the allocation of deceased donor kidneys to patients. We then discuss the requirements such policies need to meet, and focus on policies that are based on point systems or scoring rules. Finally, we review the current policy in use in the U.S. (which itself is based on a scoring rule), as well as updates on the development of a new scoring rule based national policy.

In the U.S., the non-profit *Organ Procurement Organizations* (OPOs) are directly responsible for evaluating, procuring and allocating donated organs within their respective designated service area. Once consent is obtained and an organ is procured by an OPO, the OPTN computerized national registry automatically generates a list of patients, who are medically compatible with the procured organ. Medical compatibility of patients is determined by their physiological characteristics and those of the procured organ (*e.g.*, accounting for ABO incompatibility<sup>1</sup>, weight and size, unacceptable antigens, etc.). Subsequently, the priority method used by the OPO determines the order in which the organ will be offered to patients. Once a kidney is procured, it can be typically preserved for up to 36-48 hours, after which the organ can no longer be used for transplantation. For that reason, priority is given to local patients, although there are rules that determine when priority should be given to non local patients. After an offer is being made to a patient, he has to decide with his surgeon whether to accept it or not within a limited amount of time. In case of rejection, the organ is offered to the next patient according to the specified order and so on. In case no patient accepts the organ within 36-48 hours, the organ is discarded.

In addition to using the OPTN national registry, the activities of the OPOs, and their allocation

---

<sup>1</sup>ABO incompatibility is a reaction of the immune system that occurs if two different and not compatible blood types are mixed together, see <http://www.nlm.nih.gov/medlineplus/ency/article/001306.htm>.

policies in particular, are coordinated and regulated by the OPTN. That is, the OPTN provides general guidelines and lays out a national allocation policy that is suggested to all OPOs. The allocation policy of every OPO then needs to be consistent with the national policy, although minor alterations are possible subject to approval by the OPTN.

## 2.1. National Allocation Policies

National policies for the allocation of the deceased donor kidneys are developed by the OPTN *Kidney Transplantation Committee* (KTC), and are approved by the U.S. Department of Health & Human Services. Policies need to account for numerous legal, economic, institutional, ethical, and other societal factors; the requirements for an allocation policy are included in the OPTN Final Rule (DHHS (2000)). Below we summarize the most important guidelines that policies have to conform to as per the OPTN Final Rule. In particular, the allocation

- (a) shall seek to achieve the best use of donated organs, and avoid organ wastage;
- (b) shall set priority rankings based on sound medical judgment;
- (c) shall balance medical efficiency (extra life years) and equity (waiting time), without discriminating patients based on their race, age and blood type;
- (d) shall be reviewed periodically and revised as appropriate.

Additionally, the priority method in place needs to be simple and easy to communicate, as discussed in the Introduction. As such, the ranking of patients is typically achieved by means of a *point system* or *scoring rule*: all national allocation policies that have been used in practice have been based on scoring rules. We formally define next the notion of a scoring rule based policy and then discuss the current national policy and suggested revisions.

**Point system or Scoring rule based policies.** Under a policy based on a scoring rule, patients are ranked according to a calculated score, commonly referred to in this context as the *Kidney Allocation Score* (KAS). Specifically, a scoring rule consists of *score components* and scalar constant *score weights*. A score component can be any function of the characteristics of a patient and/or an organ. Then, once an organ is procured and needs to be allocated, one calculates the individual score components for each patient and the particular procured organ. The KAS for each patient

is evaluated as the weighted sum of his score components (using the score weights). To introduce some notation, given a patient  $p$  and an organ  $o$ , we denote the  $j$ th score component with  $f_{j,(p,o)}$ , and the  $j$ th score weight with  $w_j$ . The KAS of patient  $p$  for receiving organ  $o$ ,  $\text{KAS}(p, o)$ , is then calculated as

$$\text{KAS}(p, o) = \sum_j w_j f_{j,(p,o)}.$$

For instance, examples of score components can be the number of years the patient has been registered on the waiting list for, the life expectancy of the patient in case he remained on dialysis, or the life expectancy in case he received the procured organ, etc.

One can think of a scoring rule based policy as a priority method that awards points to patients based on different criteria (the score components); patients are also potentially awarded different amounts of points per criterion, based on the score weights. The ranking is then achieved based on the number of points collected by each patient. The current policy in use and the one recently proposed by U.S. policymakers are both examples of scoring rule based policies and are discussed next.

**Current allocation policy.** The current policy has been in existence for more than 20 years. It is based on a scoring rule that utilizes waiting time, a measure of the patient’s sensitization<sup>2</sup> and tissue matching<sup>3</sup> of the organ and the patient as score components. The rationale behind this rule is as follows. Points are given for waiting time and sensitization in order to serve the fairness objective of the allocation and to provide equal access to organs to all patients (note that highly sensitized patients have reduced medical compatibility with donors). On the other hand, since tissue matching is an indication for a successful transplantation, the points given to matched patients serve the medical efficiency objective of the allocation. For more details we refer the reader to ODADK (2010).

Recent advances in medicine and changes in patients’ needs however, have rendered the current policy inappropriate. More specifically, these changes have rendered the current policy inconsistent

---

<sup>2</sup>Potential recipients are “sensitized” if their immune system makes antibodies against potential donors. Sensitization usually occurs as a consequence of pregnancy, blood transfusions, or previous transplantation. Highly sensitized patients are more likely to reject an organ transplant than are unsensitized patients. For more information, see <http://www.ustransplant.org/>

<sup>3</sup>When two people share the same human leukocyte antigens (abbreviated as HLA), they are said to be a “match”, that is, their tissues are immunologically compatible with each other. HLA are proteins that are located on the surface of the white blood cells and other tissues in the body. For more information, see <http://www.stanford.edu/dept/HPS/transplant/html/hla.html>

with the OPTN Final Rule, see Norman (2009) and RFI (2008). For instance, the long waiting times experienced by the patients, coupled with advances in medicine that have prolonged the survivability of patients on dialysis, have resulted in the accumulation of points for waiting time by the patients. This accumulation of points has then created an imbalance between the efficiency and fairness objectives of the allocation, see OPTNKTC (2007). In response to that, and in line with the requirement of the OPTN Final Rule for periodic review of the policy, the KTC has been reviewing the policy for the past few years and is currently in the process of developing a new policy, see OPTNKTC (2007).

**Development of a new policy.** Since 2004, the KTC has considered more than 40 different scoring rules, which involve various score components, see OPTNKTC (2010). We first discuss the criteria upon which the score components are based, and then discuss the components. For a patient  $p$  and an organ  $o$ , the criteria are

1. Tissue matching or HLA matches, *i.e.*, the number of HLA shared by patient  $p$  and organ  $o$ ;
2. Age of patient  $p$  and/or donor of organ  $o$ , denoted by  $AGE(p)$  and  $AGE(o)$ ;
3. Wait time, which is equal to the number of years patient  $p$  has been registered at the waitlist;
4. Dialysis time, which is equal to the years patient  $p$  has spent on dialysis, denoted by  $DT(p)$ ;
5. Blood group of patient and/or donor;
6. Expected post transplant survival of patient  $p$  from receiving organ  $o$ ;
7. Expected waitlist survival of patient;
8. Life years from transplant, denoted by  $LYFT(p, o)$ , which is equal to the expected incremental quality-adjusted life years gain of patient  $p$  from receiving organ  $o$ , compared to remaining on dialysis (for a precise definition, we refer the reader to Wolfe et al. (2008));
9. Donor profile index, denoted by  $DPI(o)$ , which is a number between 0 and 1, indicating the quality of the donated organ (0 corresponds to an organ of highest quality);
10. Calculated panel reactive antibody, denoted by  $CPRA(p)$ , which is a number between 0 and 100, measuring the sensitization of the patient (0 corresponds to the lowest level).

A typical scoring rule proposed by the KTC includes 3-5 score components that are functions of (some of) the above criteria. In most cases, the components are either linear functions (*e.g.*, points are awarded per year on dialysis, or per life year from transplant, etc.), or nonlinear functions of one or more criteria (*e.g.*, for patient  $p$  and organ  $o$ , points are awarded according to  $(1 - \text{DPI}(o)) \times \text{LYFT}(p, o)$ , or  $\text{DPI}(o) \times \text{DT}(p)$ , or  $|\text{AGE}(p) - \text{AGE}(o)|$ , etc.), including stepwise or indicator functions (*e.g.*, points are awarded if patient  $p$  is highly sensitized,  $\text{CPRA}(p) \geq 80$ , or if he is aged less than 18 or 35,  $\text{AGE}(p) \leq 18$  or 35, etc). For more details, we refer the reader to OPTNKTC (2007), OPTNKTC (2008).

As mentioned above, the KTC considered more than 40 different scoring rules, each of which utilizes a subset of the score components above. Furthermore, based on simulation experiments, the KTC evaluated the performance of the proposed scoring rules and identified weights that were deemed appropriate (see OPTNKTC (2008)). The dominant proposal up to this point, published in 2008 in a Request For Information document (RFI (2008)), entails the following score components:  $\text{LYFT} \times (1 - \text{DPI})$ ,  $\text{DT} \times \text{DPI}$ ,  $\text{DT}$  and  $\text{CPRA}$ . The associated score weights are 0.8, 0.8, 0.2 and 0.04. That is, the Kidney Allocation Score under the dominant proposal is

$$\begin{aligned} \text{KAS}(p, o) &= 0.8 \text{LYFT}(p, o) \times (1 - \text{DPI}(o)) \\ &\quad + 0.8 \text{DT}(p) \times \text{DPI}(o) \\ &\quad + 0.2 \text{DT}(p) \\ &\quad + 0.04 \text{CPRA}(p). \end{aligned}$$

The first two components are the life years from transplant and dialysis time, scaled by the donor profile index. The scaling ensures that in case of a high quality organ (DPI close to 0), emphasis is given on life years from transplant, whereas in case of a low quality organ (DPI close to 1), emphasis is given on dialysis time. The last two components are the dialysis time and calculated panel reactive antibody score of the patient. More information and motivating aspects can be found within the Request For Information document (RFI (2008)). As an example, consider an organ  $o$  of medium quality, with  $\text{DPI}(o) = 0.55$ . Then, patients are awarded  $0.8 \times (1 - 0.55) = 0.36$  points for every quality adjusted incremental life year they would gain in expectation,  $0.8 \times 0.55 + 0.2 = 0.64$  points for every year they have spent on dialysis, and 0.04 points for every point of their CPRA

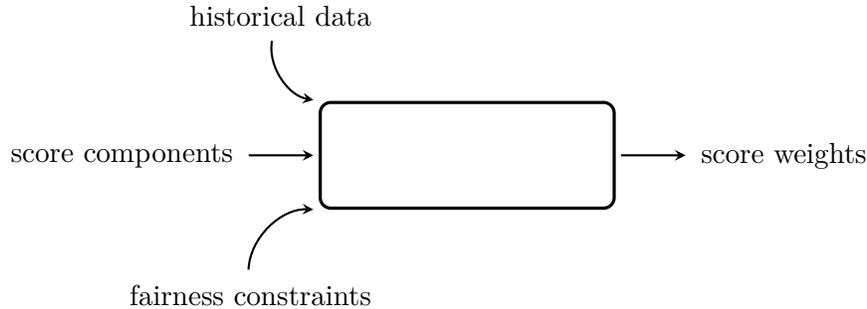

score.

While medical expertise and the OPTN Final Rule can guide the identification of the score components of clinical validity, the task of finding the right selection or subset of these components and the appropriate weights is more involved, as the experimentation of the OPTN KTC with more than 40 different rules suggests. A natural question in response to the proposed scoring rule is whether this is the best we can do. In particular, does there exist another scoring rule of the same format, based on the criteria and score components considered by policymakers, that dominates the proposed one, *i.e.*, is equally or more fair and more efficient? Admittedly, this is an involved question to answer; to illustrate this, consider only changing the weights in the proposed scoring rule above. The outcomes by such a change can perhaps be evaluated only via simulation; simulating a single specific scoring rule takes hours. This severely curtails the efficacy of a search for a policy that while possessing the requisite fairness properties is also efficient. Our proposed methodology provides a valuable tool in this search and takes a step towards answering the questions posed above.

### **3. Designing Allocation Policies**

We propose a method for designing scoring rule based policies for the allocation of deceased donor kidneys to patients. Specifically, we propose a data-driven method that computes in a systematic way score weights associated to pre-specified score components, so that the resulting policy achieves a near-optimal medical utility (measured by life years from transplant gains). In other words, after one has decided upon the components he wishes to include in a scoring rule, our method utilizes historical data to efficiently compute associated weights, so as to maximize the efficiency of the policy. In addition, our method can also take as input fairness constraints on the allocation outcomes; while we defer the precise definition of the class of admissible constraints for Section 3.1, we note here that our method captures a multitude of important and commonly studied constraints of interest to policymakers. Then, the method computes the score weights, so that the resulting policy is as efficient as possible, and the fairness constraints are approximately satisfied.

Figure 1 illustrates the functionality of the proposed method. Typically, policymakers select their desired score components that would feature in the scoring rule and constraints that the allocation outcomes need to satisfy. Our method provides an efficient, scalable and systematic

**Figure 1:** An illustration of the functionality of the proposed method.

way of striking the right balance between the selected score components by designing a policy that approximately maximizes medical efficiency, subject to the selected constraints.

As an application of our method, we use historical data from 2008, to construct multiple scoring rule based policies that utilize the same criteria for components as the ones considered by the OPTN Kidney Transplantation Committee. Within the different case studies we present, we also design a policy that possesses similar fairness characteristics with the KTC dominant proposal. Numerical studies then suggest that this policy constructed by our method achieves an 8% improvement in life years from transplant, using the same statistical and simulation tools and data as U.S. policymakers use. Furthermore, we perform a trade-off analysis by considering deviations from the fairness constraints of the proposed policy. In particular, we study the effect in life year gains of the policy, in case of emphasizing or deemphasizing the priority given to patients who have been waiting for a long time or are sensitized. Our method efficiently redesigns policies accordingly. The results indicate that the performance gain in life years from transplant can be as high as 30%. Details on the case and simulation studies are included in Section 4.

We next present our proposal in full detail.

### 3.1. Methodology

Given a list of  $n$  score components, related historical data of patients' and donated organs' characteristics, and constraints on the allocation outcomes (precisely defined below), we calculate score weights  $w_1, \dots, w_n$ , such that the resulting scoring rule policy satisfies the constraints approximately, while maximizing life years from transplant.

Consider a fixed time period over which we have complete (ex facto) information about all patients registered in the waitlist (pre-existing and arriving) in that time period. In particular,

we know their physiological characteristics, the time of their initial registration, as well as the evolution of their medical status and availability for a transplant during that time period. Suppose we also have complete information about the organs that are procured during the period, that is the time at which they are procured and their physiological characteristics. We index the patients by  $p = 1, \dots, P$  and the organs by  $o = 1, \dots, O$ . We say that patient  $p$  is *eligible* to receive organ  $o$ , or equivalently that the patient-organ pair  $(p, o)$  is eligible for transplantation, if at the time of the organ procurement all conditions below are met:

1. The patient is registered at the waitlist for a transplant;
2. The patient is actively waiting for a transplant and his medical status is appropriate for transplantation;
3. The patient is medically compatible with the organ.

Let  $\mathcal{C}$  be the set of patient-organ pairs eligible for transplantation, *i.e.*,

$$\mathcal{C} = \{(p, o) : \text{patient } p \text{ is eligible to receive } o\}.$$

Note that one can construct  $\mathcal{C}$  simply by using the arrival information and characteristics of the organs and the patients, and the evolution of the availability and medical status of the patients.

Additionally, one can also compute the score components for each eligible patient-organ pair, as well as the life years from transplant. Let  $f_{j,(p,o)}$  be the value of the  $j$ th component score,  $j = 1, \dots, n$ , and LYFT( $p, o$ ) the life years from transplant for pair  $(p, o) \in \mathcal{C}$ .

We now define the class of admissible constraints on the allocation outcomes, alluded to thus far. First, let  $x_{(p,o)}$  be defined for every eligible patient-organ pair  $(p, o)$  as

$$x_{(p,o)} = \begin{cases} 1, & \text{if organ } o \text{ is assigned to patient } p, \\ 0, & \text{otherwise.} \end{cases}$$

A constraint is admissible for our method if it is *linear*, that is if it can be modeled as a linear constraint with respect to variable  $x$ . The class of constraints that can be modeled in this way is very broad, and captures the majority of constraints a policymaker might wish to incorporate; for instance, one can impose lower bounds for a specific group of patients on

- the probability of receiving a transplant,
- the average life years from transplant gained among the actual transplant recipients,
- the average time spent on dialysis among the actual transplant recipients.

As an example, a lower bound  $L$  on the number of organs allocated to a specific group of patients  $\mathcal{G} \subset \{1, \dots, P\}$ , can be expressed as

$$\sum_{p \in \mathcal{G}} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} \geq L.$$

For instance, setting  $\mathcal{G}$  to be the set of all patients of blood type O could enforce a lower bound on transplants for patients of this blood type.

We denote the input fairness constraints with  $Ax \leq b$ , for some matrix  $A$  and vector  $b$ . We now present our method which consists of three steps:

**Step 1 (An Idealized Matching Problem):** Consider a social planner with foresight who has knowledge of the set of all eligible pairs  $\mathcal{C}$  and the life years from transplant score for every pair in the set. Suppose also that patients accept all organs offered to them. In this setup, the problem of allocating organs to patients so as to maximize medical efficiency, *i.e.*, life years from transplant, subject to fairness constraints  $Ax \leq b$ , can be formulated as a linear optimization problem:

$$\begin{aligned} & \text{maximize} && \sum_{(p,o) \in \mathcal{C}} \text{LYFT}(p,o)x_{(p,o)} \\ & \text{subject to} && \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} \leq 1, \quad \forall p \\ & && \sum_{p: (p,o) \in \mathcal{C}} x_{(p,o)} \leq 1, \quad \forall o \\ & && Ax \leq b \\ & && x \geq 0. \end{aligned} \tag{1}$$

Note that a fractional value for  $x_{(p,o)}$  can be interpreted as the probability of assigning organ  $o$  to patient  $p$  in a randomized policy. It's solution suggests an allocation with perfect hindsight (as opposed to an implementable policy). The next two steps will use this idealized solution to construct an implementable policy in a unique way.

**Step 2 (Dual Information):** By linear optimization duality, if  $y$  is the vector of optimal dual

multipliers associated with the constraints  $Ax \leq b$  for problem (1), then problem (1) is equivalent with the one below:

$$\begin{aligned}
& \text{maximize} && \sum_{(p,o) \in \mathcal{C}} \text{LYFT}(p,o)x_{(p,o)} - y^T Ax + y^T b \\
& \text{subject to} && \sum_{o:(p,o) \in \mathcal{C}} x_{(p,o)} \leq 1, \quad \forall p \\
& && \sum_{p:(p,o) \in \mathcal{C}} x_{(p,o)} \leq 1, \quad \forall o \\
& && x \geq 0.
\end{aligned} \tag{2}$$

Note that problem (2) is a matching problem. We equivalently rewrite the objective of (2) as  $c^T x + y^T b$ , utilizing the cost vector  $c$  defined as

$$c_{(p,o)} = \text{LYFT}(p,o) - (y^T A)_{(p,o)}, \quad \forall (p,o) \in \mathcal{C}.$$

We next use this dual information to construct an implementable policy.

**Step 3 (Approximate Dynamic Programming):** Note that our goal is to design a policy that approximately solves the above matching problem online, *i.e.*, a policy that sequentially matches organs at their time of procurement to available patients without utilizing any future information. An implementable policy will require the following:

1. An estimate of the value of assigning a particular organ,  $o$  to a particular patient,  $p$  (technically, one may think of this as a differential value function for the associated stochastic optimization problem).
2. An interpretable formula for the above differential value that uses permissible features of the patient and organ in a clinically acceptable way. Our goal is to rank patients not by any artificial score coefficients, but rather based on the selected score components.

One possible policy is scoring potential allocations on the basis of the coefficients  $c_{(p,o)}$  computed above. Unfortunately, the  $c_{(p,o)}$  coefficients are calculated for patients on the waiting list and received organs from some historical data set and as such it is likely that we will not have access to  $c_{(p,o)}$  for all pairs  $(p,o)$  moving forward. More importantly, a scoring policy based on these coefficients will not satisfy the second requirement above. As such, we consider using the coefficients

to inform the calibration of an acceptable scoring rule. In particular we find acceptable score weights  $w$  by solving the optimization problem

$$\begin{aligned} & \text{minimize} && \sum_{(p,o) \in \mathcal{C}} \left( c_{(p,o)} - w_0 - \sum_{j=1}^n w_j f_{j,(p,o)} \right)^2 \\ & \text{subject to} && w \in \mathcal{S}, \end{aligned}$$

where the set  $\mathcal{S}$  enforces clinical and ethical requirements (for instance, by requiring that the resulting policy be continuous or monotone in certain score components, etc.).

The method is summarized as Procedure 1.

---

**Procedure 1** Computation of score weights

---

**Input:** list of  $n$  score components, data for linear constraints  $(A, b)$ , historical data: set of eligible patient-organ pairs  $\mathcal{C}$ , life years for transplant  $\text{LYFT}(p, o)$  and values of score components,  $f_{j,(p,o)}$ ,  $j = 1, \dots, n$ , for every eligible pair  $(p, o)$ .

**Output:** weights for scoring rule,  $w_1, \dots, w_n$ .

- 1: solve problem (1)
- 2:  $y \leftarrow$  vector of optimal dual multipliers associated with constraints  $Ax \leq b$
- 3:  $c_{(p,o)} \leftarrow c_{(p,o)} = \text{LYFT}(p, o) - \left( y^T A \right)_{(p,o)}$ ,  $\forall (p, o) \in \mathcal{C}$
- 4: use (potentially constrained) linear regression to find  $w_0, w_1, \dots, w_n$ , such that for all  $(p, o) \in \mathcal{C}$

$$c_{(p,o)} \approx w_0 + w_1 f_{1,(p,o)} + \dots + w_n f_{n,(p,o)}.$$

---

### 3.2. Discussion

In this section, we discuss (a) why one should expect the proposed method to perform well in practice, and (b) the relative merits of our contribution.

Consider the airline network revenue management setting analyzed in Talluri and van Ryzin (1998). In that setting, an airline is operating flights and is selling different itinerary tickets to incoming customers, so as to maximize net expected profits from sales subject to capacity constraints (which correspond to the numbers of seats on the different aircrafts operating the flights). The authors analyze a simple control policy that decides whether to sell an itinerary ticket to a passenger or not, and demonstrate that the policy is asymptotically optimal under some conditions. For the organ allocation problem, a simplified version of the policy that we described in the previous section can be cast in the same framework as in Talluri and van Ryzin (1998);

one can then derive a similar result of asymptotic optimality, following the same procedure. In particular, in Talluri and van Ryzin (1998), the authors analyze the performance of the following simple bid-price control policy: one first solves a capacity allocation problem assuming that demand is deterministic and equal to the mean demand. Based on the optimal dual multipliers associated with the resource capacity constraints in that problem, one then calculates a “bid price” for every unit of a particular resource. An itinerary ticket is then sold to a customer if the money offered by the customer exceed the sum of prices of the resources he would consume. In our procedure, if we ignore the regression step, we also assume deterministic demand and solve a similar allocation problem<sup>4</sup>. We then calculate “bid prices”  $y$  associated to the fairness constraints and assign the organ to the patient who achieves the highest profit (LYFT), adjusted for the “bid prices”. For more details, we refer the reader to the paper by Talluri and van Ryzin (1998).

Apart from the above discussion regarding the performance of our method in practice, we next provide numerical evidence. Before that, we summarize the relative merits of our contribution.

1. The proposed method uses detailed historical medical data to extract near optimal score weights in an efficient manner. In particular, the method is highly scalable and can learn the parameters from potentially highly detailed and complicated historical datasets, with no need for simplifications, clustering or grouping of patients’ and/or organs’ characteristics.
2. The method offers the flexibility and allows policymakers to focus only on identifying score components and desired fairness properties of allocation outcomes in the design of a new policy. The method undertakes the more involved part of finding the appropriate weights and balancing the score components. Although medical intuition can help in making educated guesses for the weights, there is little guarantee that a policy designed in such way would yield the desired results. Furthermore, even if a set of weights yields a policy with the desired outcomes, there can be another policy delivering a superior performance. Due to the computational intensity of simulations, one simply cannot explore all possible combinations of weights. Our contribution is towards this direction, by using mathematical tools to automatically extract near-optimal weights from historical data.

---

<sup>4</sup>Specifically, consider the deterministic linear optimization model analyzed in Talluri and van Ryzin (1998), where the different customer classes correspond to patient classes, the profits correspond to life years from transplant and the network capacity constraints correspond to the fairness constraints. If we instead use historical samples rather than averages, we recover formulation (1).

3. From a methodological perspective our approach can be seen as a contribution to approximate dynamic programming techniques in general and bid-pricing methodologies for dynamic allocation in particular. More precisely, bid pricing methodologies exist for the dynamic allocation of a potentially large set of objects arriving randomly over time and each of which can be classified into a *small* number of distinct types, to a small set of bins, each with potentially large capacity. In the kidney allocation context the heterogeneity in patients and organs precludes classifying either into a small number of types. Our methodology shows how to deal with this problem and in general extends bid price methodologies to scenarios where arriving objects and “bins” are highly heterogeneous.
4. The failure of the current kidney allocation policy in place to keep up with advances in medicine and the changes in patients’ needs throughout the years, has demonstrated that in such a dynamic and complex environment, revisions to policies are likely to be required in the future as well, a fact that is also recognized by the OPTN Final Rule. Furthermore, even in the current process of developing a new policy, there is no guarantee that the Office of Civil Rights will approve the criteria of life years from transplant, dialysis time, etc., suggested by the OPTN policymakers. In both cases, our method will expedite the development of a new policy, as it would require only an updated list of score components and fairness properties to be specified.
5. Our method allows for sensitivity analysis; specifically, one can efficiently evaluate the outcomes of relaxing some or introducing new fairness constraints. In the next section, we provide such an analysis that reveals the dependence of medical efficiency on fairness concepts, and illustrate how it can be used in practice by policymakers. In particular, note that one of the main goals that the OPTN policymakers have set for a new national policy is to deemphasize the role of waiting time and increase medical efficiency (see Section 2.1). Our analysis provides a characterization of the trade-offs involved.

In the next section, we provide numerical evidence of the usefulness of the described method. In particular, we use historical data to design multiple new scoring policies under different scenarios and also perform a sensitivity analysis.

## 4. Numerical Evidence and the Design of New Allocation Policies

We utilize the method described in the previous section to design new scoring-rule based policies for kidney allocation that have different fairness requirements and/or are based on different score components. Specifically, we consider various fairness requirements and score components derived from policies that have been proposed by the OPTN Kidney Transplantation Committee (see Section 2.1), to set up 4 realistic case studies. Briefly, the intent and outcomes of these case studies are as follows:

1. **Case Study 1:** Here we demonstrate the utility of our approach in finding policies using *precisely* the set of score components utilized by the current dominant proposal considered by the KTC (referred to also as the KTC policy or proposal in this section). Using the methodology of the previous section we require the approach to preserve the fairness properties of the dominant proposal. In addition to finding a policy that is *de facto* clinically valid in an automated fashion, the policy designed provides life year gains of approximately 3% relative to the dominant proposal, *in spite* of being so heavily constrained. This demonstrates the value of the approach in designing policies given requirements on fairness, and a small set of score-components.
2. **Case Study 2:** Here we allow policies that can potentially be based on all score components considered by policy makers but continue to require the fairness properties of the dominant proposal. As described in the previous Section, we impose constraints on our methodology to guarantee that the resulting scoring rule is clinically valid. Our methodology produces a policy that in addition to being clinically valid and exhibiting similar fairness properties as the dominant proposal provides an 8% increase in life year gains relative to that proposal. In addition to the merits exhibited via the first case study, this demonstrates the value of the approach vis-a-vis the task of guiding the selection of a small but appropriate set of score components from a large family of potential score components.
3. **Case Studies 3 and 4:** Similar to the previous study, this study requires fairness criteria that correspond to a perhaps more balanced allocation of organs among different age groups of patients (as opposed to the dominant proposal which has been criticized as providing too few transplants to older age groups). Surprisingly, we develop a clinically acceptable policy

that allays these criticisms of the dominant proposal while providing essentially the same life years gains as the dominant proposal. This demonstrates the value of our methodology vis-a-vis designing policies that must satisfy stringently specified fairness criteria. We further consider various relaxations of the fairness criteria and construct corresponding policies to show how our approach allows policy makers to perform a sensitivity analysis relative to fairness requirements.

To ensure a fair comparison, we evaluate the performance of all policies we study by using the same statistical models and tools, as well as datasets with the OPTN KTC policymakers. We first provide details about the data and models, and then present our methodology and results.

#### **4.1. Data, Statistical Models and Tools**

This work uses highly detailed historical data from the Scientific Registry of Transplant Recipients (SRTR). The SRTR data system includes data on all donor, wait-listed candidates, and transplant recipients in the U.S., submitted by the members of the Organ Procurement and Transplantation Network (OPTN). The datasets include all the various physiological and demographic characteristics of wait-listed patients and donors that are needed for our study, as well as the evolution of the medical status of the patients, and the arrival process of the donated organs.

In addition, the SRTR has developed sophisticated survivability models for ESRD patients using historical survival rates. The models provide an estimate for the anticipated lifespan of a patient in case he remained on dialysis, or in case he received a particular kidney, based on a plethora of physiological attributes (*e.g.*, the patient’s age, body mass index, diagnosis, as well as tissue matching, the donor’s age, cause of death, etc.). For more information and a detailed study of the statistical performance of the models, we refer the reader to Wolfe et al. (2008) and Wolfe et al. (2009). The SRTR has also developed an acceptance model that predicts the probability of a particular patient accepting a particular organ offered to him, based on the physiological characteristics of the patient and the donor, the distance, etc.

The above datasets and statistical models have also been utilized by the SRTR in the development of the *Kidney-Pancreas Simulated Allocation Model* (KPSAM). The KPSAM is an event-driven simulator that simulates the entire allocation process using historical data, for different allocation policies. It was developed in order to support studies of alternative policies. The KP-

SAM is the platform that the OPTN KTC is utilizing to evaluate the performance of their proposed policies, see OPTNKTC (2007). For more details on the data and the simulator, we refer the reader to Waisanen et al. (2004) and KPSAM (2008).

For the purposes of this study, we obtained the KPSAM and utilized its simulation engine in order to obtain realistic allocation outcomes of the policies we consider. The life years from transplant gains are estimated using the aforementioned survivability models, embedded in the KPSAM.

## 4.2. Methodology

We perform 4 case studies of designing scoring rules that have different fairness requirements and/or are based on different score components. In all studies we design allocation policies using our method described in Section 3. Recall that our method outputs scoring rules, given as input historical data, fairness requirements and score components. We discuss the specific fairness requirements and score components of each case study separately (see below). For historical data, we use the first 6 months of data of the 2008 SRTR database as input to our method (training data).

To evaluate the performance of a policy, we use the KPSAM to simulate the allocation outcomes of that policy 100 times, over the remaining 6 months of the 2008 dataset that were not used as training data. To evaluate efficiency, we record the average number of transplantations occurring and the average net expected life years from transplant (along with sample standard deviation). To compare fairness properties across different policies, we compare the percentage distribution of transplant recipients across different races, age groups, blood types, sensitization groups, as well as diagnosis types and years spent on dialysis. Note that this practice is in line with the comparison criteria studied by the OPTN policymakers (see OPTNKTC (2008), RFI (2008)). As such, we also record the average aforementioned percentage distributions for the 100 simulation runs (along with sample standard deviations).

We next present the case studies and discuss our results. In the first study, we design a policy that utilizes the exact same score components as the dominant KTC policy, while exhibiting the same fairness properties. Similarly, we also design a policy that is based on the exact same score components as another policy considered by the KTC. In the second and third case studies, we consider all score components and criteria studied by the KTC (see Section 2.1), and actually use

our method to select a subset of them, while enforcing the same fairness properties as the KTC policy (Case Study 2), or alternative fairness properties (Case Study 3). The fourth case study deals with a trade-off analysis, where we further study deviations from the fairness properties of the KTC proposed policy and their consequences to efficiency.

### 4.3. Case Study 1

We design two policies that are based on the same score components as two specific policies proposed by KTC, including the dominant proposal. We enforce the policies to have the same fairness properties as the dominant KTC proposal.

**Score components.** We use (a) the same score components as in the KTC policy, namely  $(1 - \text{DPI}) \times \text{LYFT}$ ,  $\text{DPI} \times \text{DT}$ ,  $\text{DT}$ ,  $\text{CPRA}$ , and (b) the same score components as in another KTC proposed policy<sup>5</sup>, namely  $(1 - \text{DPI}^2) \times \text{LYFT}$ ,  $\text{DPI}^2 \times \text{DT}$ ,  $\text{DT}$ ,  $\text{CPRA}$ .

**Fairness constraints.** We require the two policies to have the same fairness properties as the dominant KTC proposal. To enforce that, we simulate the KTC policy and record the percentage distribution of transplant recipients across the different groups discussed above. We then use those recorded percentage distributions as input constraints. More specifically we use them to input lower bound constraints on the percentage of organs allocated to the following groups: Caucasian, African-American, Hispanic or patients of another race; patients aged between 18-35, 35-50, 50-65 and above 65 years; patients who have spent less than 5, 5-10, 10-15 or more than 15 years on dialysis; blood type O, A, B, AB patients; patients diagnosed with nephritis, hypertension, polycystic kidney disease, diabetes or other disease; patients with a sensitization level (CPRA) of 0-10, 10-80 or 80-100. For instance, consider the fairness constraints pertaining to dialysis time. The recorded percentage distribution of recipients for the KTC policy is as follows: 54% of the recipients have spent less than 5 years on dialysis, 29.5% between 5-10 years, 11.1% between 10-15

---

<sup>5</sup>One of the policies considered by the KTC entailed an allocation score similar to the score of the dominant KTC policy, but with the DPI term replaced by  $\text{DPI}^2$ .

	KTC policy	Case Study 1(a)	Case Study 1(b)
number of transplantations (std)	5,799 (23)	5,801 (21)	5,497 (22)
net life years from transplant (std)	34,217 (185)	35,134 (187)	34,764 (189)

**Table 1:** Simulation results of the KTC policy and the policies designed in Case Study 1 in Section 4.3, for an out-of-sample period of 6 months in 2008 and 100 runs.

years and 5.4% more than 15 years. The constraints we add then as input to our method are:

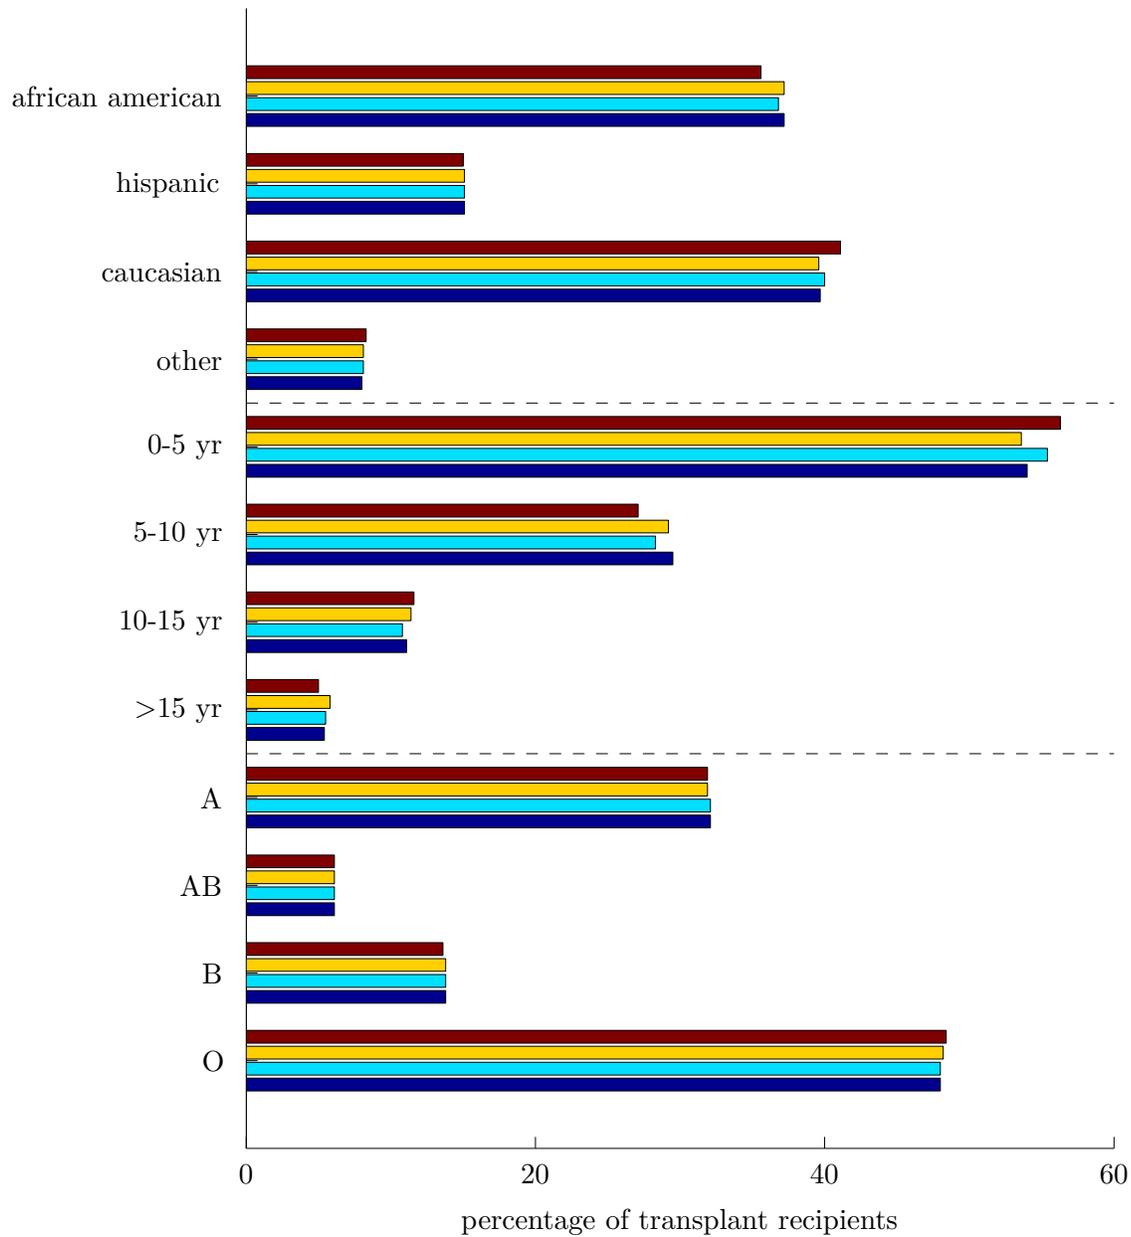

$$\begin{aligned}
\sum_{p: 0 \leq DT(p) \leq 5} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} &\geq \frac{54}{100} \sum_{(p,o) \in \mathcal{C}} x_{(p,o)}, \\
\sum_{p: 5 \leq DT(p) \leq 10} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} &\geq \frac{29.5}{100} \sum_{(p,o) \in \mathcal{C}} x_{(p,o)}, \\
\sum_{p: 10 \leq DT(p) \leq 15} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} &\geq \frac{11.1}{100} \sum_{(p,o) \in \mathcal{C}} x_{(p,o)}, \\
\sum_{p: DT(p) \geq 15} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} &\geq \frac{5.4}{100} \sum_{(p,o) \in \mathcal{C}} x_{(p,o)}.
\end{aligned} \tag{3}$$

**Results.** The output of our method is the scoring rule assigning the Kidney Allocation Score to a patient-organ pair  $(p, o)$  of

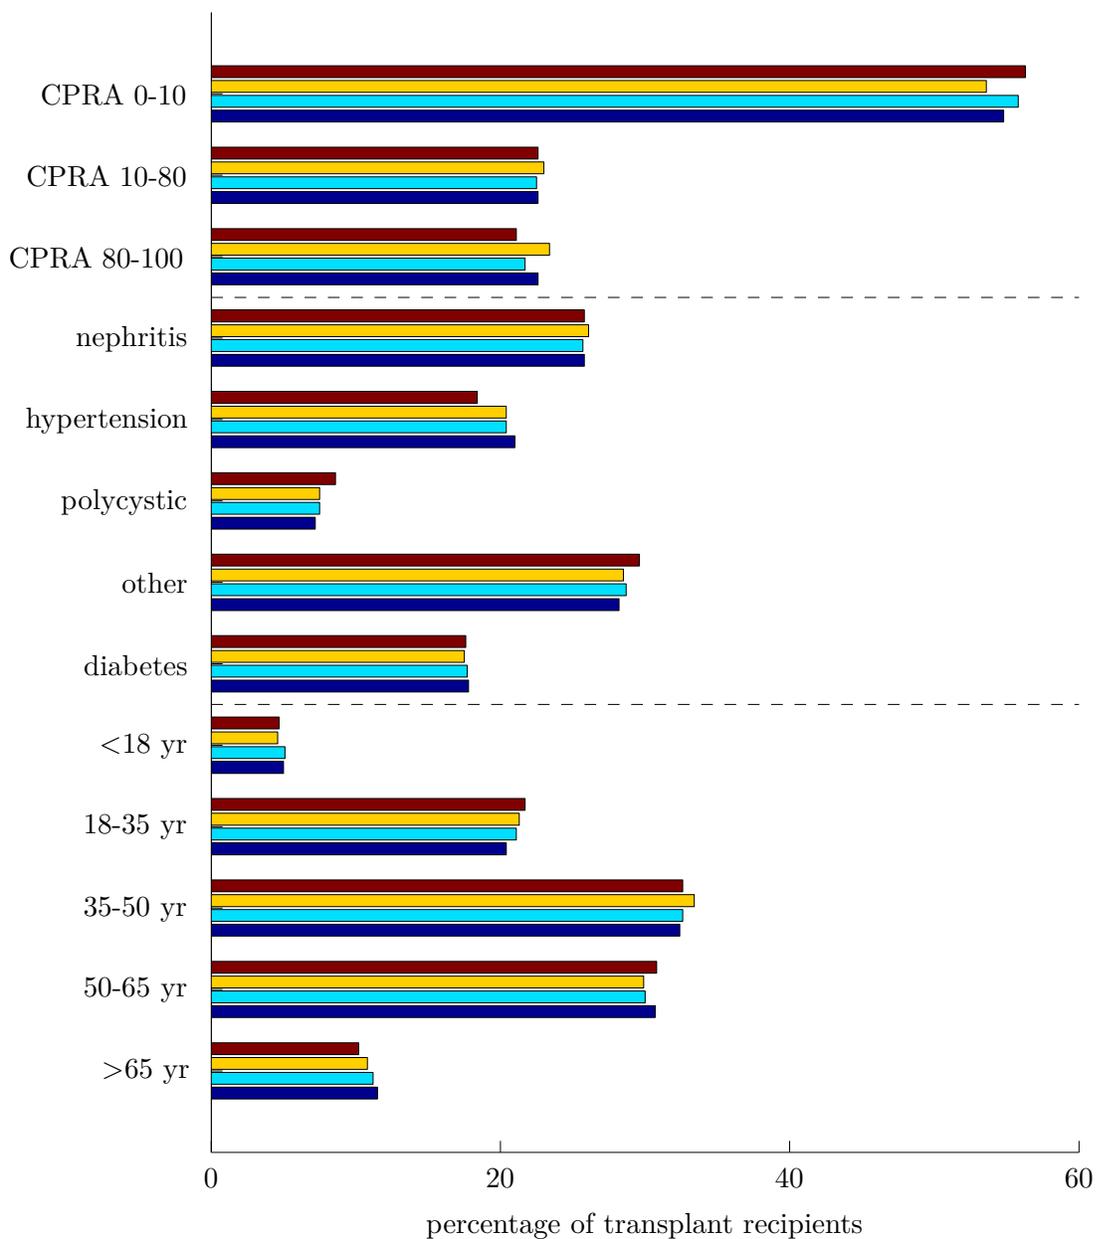

$$\begin{aligned}
\text{(a) } KAS(p, o) &= LYFT(p, o) \times (1 - DPI(o)) + 0.6 DT(p) \times DPI(o) + 0.3 DT(p) + 0.04 CPRA(p), \\
\text{(b) } KAS(p, o) &= LYFT(p, o) \times (1 - DPI(o)^2) + 0.6 DT(p) \times DPI(o)^2 + 0.6 DT(p) + 0.08 CPRA(p).
\end{aligned}$$

for the two cases we consider. In Table 1 we report simulation results for those policies, as well as the KTC policy (for comparison). In particular, we report the average number of transplantations occurring and the average net life year gains for the 3 policies, together with sample standard deviation. Figures 2 and 3 depict the simulated average percentage distributions of recipients across different patient groups (as discussed in Methodology above). Sample standard deviations for the percentage distributions are included in the Appendix.

**Discussion.** The two policies we have designed depend, respectively, on precisely the *same* score components as do the original policies proposed by KTC and have similar fairness properties (in matching the percentage distributions of recipients among different patient groups). At the same time, the policy designed using the score components of the dominant policy manages to provide a 3% increase in life year gains relative to the dominant proposal.

**Figure 2:** Simulated average percentage distributions of recipients across different race, dialysis time and blood type patient groups for the benchmark KTC policy (blue) and the policies designed in Sections 4.3-4.4, *i.e.*, in Case Study 1(a) (cyan), in Study 1(b) (yellow) and in Study 2 (red). The results are for an out-of-sample period of 6 months in 2008.

**Figure 3:** Simulated average percentage distributions of recipients across different sensitization, diagnosis and age patient groups for the benchmark KTC policy (blue) and the policies designed in Sections 4.3-4.4, *i.e.*, in Case Study 1(a) (cyan), in Study 1(b) (yellow) and in Study 2 (red). The results are for an out-of-sample period of 6 months in 2008.

This case then demonstrates that our method reliably designs policies that perform well based on input that is directly related to outcomes (fairness constraints) and permissible score components. In contrast, given a set of score components, the approach of policymakers in designing policies has traditionally been to first identify weights and then observe (simulation based) outcomes; and then go through those steps multiple times if necessary. This is obviously not ideal; a fact demonstrated amply by policy (a) designed via our methodology above. Thus, our contribution enables the design of policies in a more natural and powerful way by considering the desired outcomes directly. In the next case study we show how our method can be used to select appropriate score components as well.

#### 4.4. Case Study 2

In this case study, we design a policy that has the same fairness properties as the dominant KTC policy and is based on criteria and score components considered by the KTC. Specifically, we allow the policy to use any (small) subset of those criteria and components. In addition by imposing the appropriate constraints in the third (regression) phase of our methodology we ensure that the resulting policies are clinically valid (*i.e.*, they conform qualitatively to features of past KTC policies/ recommendations).

**Score components.** Rather than pre-selecting specific score components, we feed the regression step of our method with virtually all score components considered by the KTC (see Section 2.1). However, in accordance with the format of KTC policies, we eventually pick only the 4 most significant components, which prove to be: LYFT, a *continuous* piece-wise linear function of DT (with potential break points at 5 and 10 years), CPRA and a step-wise function of patient age (with potential break points at 50 and 65 years) that gives additional points for passing 50 years of age, and 65 years of age. These last two score components are in line with KTC proposals, and in fact, make the policy highly desirable by addressing certain ethical issues raised over equity across age groups as we discuss later.

**Fairness constraints.** As in Case Study 1, we enforce the policy to have the same fairness properties as the dominant KTC policy.

**Results.** The output of our method is the scoring rule assigning the Kidney Allocation Score to a

	KTC policy	Case Study 2	Case Study 3
number of transplantations (std)	5,799 (23)	5,807 (22)	5,822 (24)
net life years from transplant (std)	34,217 (185)	36,890 (219)	34,065 (212)

**Table 2:** Simulation results of the KTC policy and the policies designed in Case Studies 2 and 3 in Sections 4.4-4.5, for an out-of-sample period of 6 months in 2008 and 100 runs.

patient-organ pair  $(p, o)$  of

$$\text{KAS}(p, o) = \text{LYFT}(p, o) + g(\text{DT}(p)) + 0.08 \text{CPRA}(p) + 0.5 \mathbf{I}(\text{AGE}(p) \geq 50),$$

where  $\mathbf{I}$  is the indicator function and

$$g(\text{DT}) = \begin{cases} 0.65 \text{DT}, & 0 \leq \text{DT} \leq 5, \\ \text{DT} - 1.75, & 5 \leq \text{DT} \leq 10, \\ 0.2 \text{DT} + 6.25, & 10 \leq \text{DT}. \end{cases}$$

According to the above scoring rule, patients are awarded 1 point for every life year from transplant gain, 0.08 points per point of their sensitization score, 0.5 points if aged more than 50 and points based on their dialysis time as follows: 0.65 points for the first 5 years, 1 point for every additional year up to 10 years and 0.2 points for every additional year beyond that.

The simulation results are reported in Table 2 and Figures 2, 3. Sample standard deviations for the percentage distributions are included in the Appendix.

**Discussion.** In this case study we attempt to address the question: given all the score components and criteria we can use and the fairness properties of the KTC policy, can we design a policy that is based on some of those components, has the same fairness properties but is more efficient? The results demonstrate that our method is indeed capable of doing so, as the policy we design delivers an 7.8% increase in life year gains in comparison to the KTC policy. The score components our policy uses are all based on components and criteria the KTC has already considered and are discussed next.

The designed policy awards points according to life years from transplant (LYFT), dialysis time (DT), sensitization level (CPRA). The policy also uses a step-wise score component based on patient age that has the same form as the component pertaining to sensitization in the current

policy in use, see UNOS (2010). Note also that the policy uses patient age in a manner that allays critiques of earlier KTC proposals. In particular, age has been used by the KTC primarily to direct more or higher quality organs to younger patients for efficiency purposes. For instance, the allocation policy currently in use in the U.S. gives priority to pediatric patients (aged less than 18 years) for organs procured from donors aged less than 35, whereas proposals suggest to extend priority to patients aged less than 35 as well. This may be perceived as providing an undue advantage to younger patients. In contrast, the way our policy utilizes age is in the other direction. That is, to impose fairness, the policy awards points to patients aged more than 50 to compensate for the fact that they typically obtain smaller LYFT scores.

Futhermore, note that the score component pertaining to DT is continuous piece-wise linear. We present here the use of a piece-wise linear function for the following reasons: (a) to illustrate how our method can deal with a variety of functions for score components, and (b) the preference of some members of the KTC for continuous functions<sup>6</sup>, due to the concern that discontinuities might grant patients who are slightly above a particular threshold (or breakpoint) a disproportionate advantage compared with patients slightly below that threshold, see OPTNKTC (2007). Note however, we found that in all policies presented in this work, one can interchangeably use step-wise and piece-wise functions (delivering statistically indistinguishable performance).

Finally, this case study demonstrates how our method is capable of calibrating multiple score components simultaneously and distilling the ones that are important. In the absence of an algorithmic method, such a task might be strenuous or even impossible to carry out.

### 4.5. Case Study 3

We present a case study similar to Case Study 2, but with different fairness requirements. We enforce the same fairness properties with the KTC policy, but require the percentages of recipients aged 50-65 and above 65 to be equal to the percentages of patients at the waitlist aged 50-65 and above 65 respectively. This requirement results in an (additive) increase of around 17 percentage points for organs allocated to patients aged 50 and above. This increase is balanced by a pro-rata decrease in the number of organs allocated to recipients aged between 18 and 50. We require this at the outset in response to comments made by a UNOS Ethics Committee in OPTNKTC

---

<sup>6</sup>However, note that step-wise score components are utilized in the current allocation policy.

(2008) that observed that the dominant KTC proposal resulted in a *decrease* in the proportion of transplants among patients in the 50-65 and 65 and older age groups. The question that remains is whether the life year gains provided by the dominant proposal can be retained using a clinically acceptable policy that unlike the dominant proposal, does *not* result in a large change in the fraction of transplants among older age groups.

**Score components.** As in Case Study 2, we use LYFT, a piece-wise linear function of DT (with break points at 5 and 10 years), CPRA and a step-wise function of patient age (with break points at 50 and 65 years).

**Fairness constraints.** We enforce the policy to have the same fairness properties as the dominant KTC policy, but with a different age distribution requirement. In particular, the percentage distribution of patients according to age for the KTC policy is: 5% for patients aged less than 18, 20.4% for patients aged 18-35, 32.4% for patients aged 35-50, 30.7% for patients aged 50-65 and 11.5% for patients aged above 65. For our policy, we require the percentages of organs allocated to patients aged 50-65 and above 65 to be 41% and 17.8% respectively (note that those were precisely the percentages of patients aged 50-65 and above 65 in the waitlist in 2008). Accordingly, we require the percentages of organs allocated to patients aged 18-35 and 35-50 to be 14% and 22.2% respectively.

**Results.** The output of our method is the scoring rule assigning the Kidney Allocation Score to a patient-organ pair  $(p, o)$  of

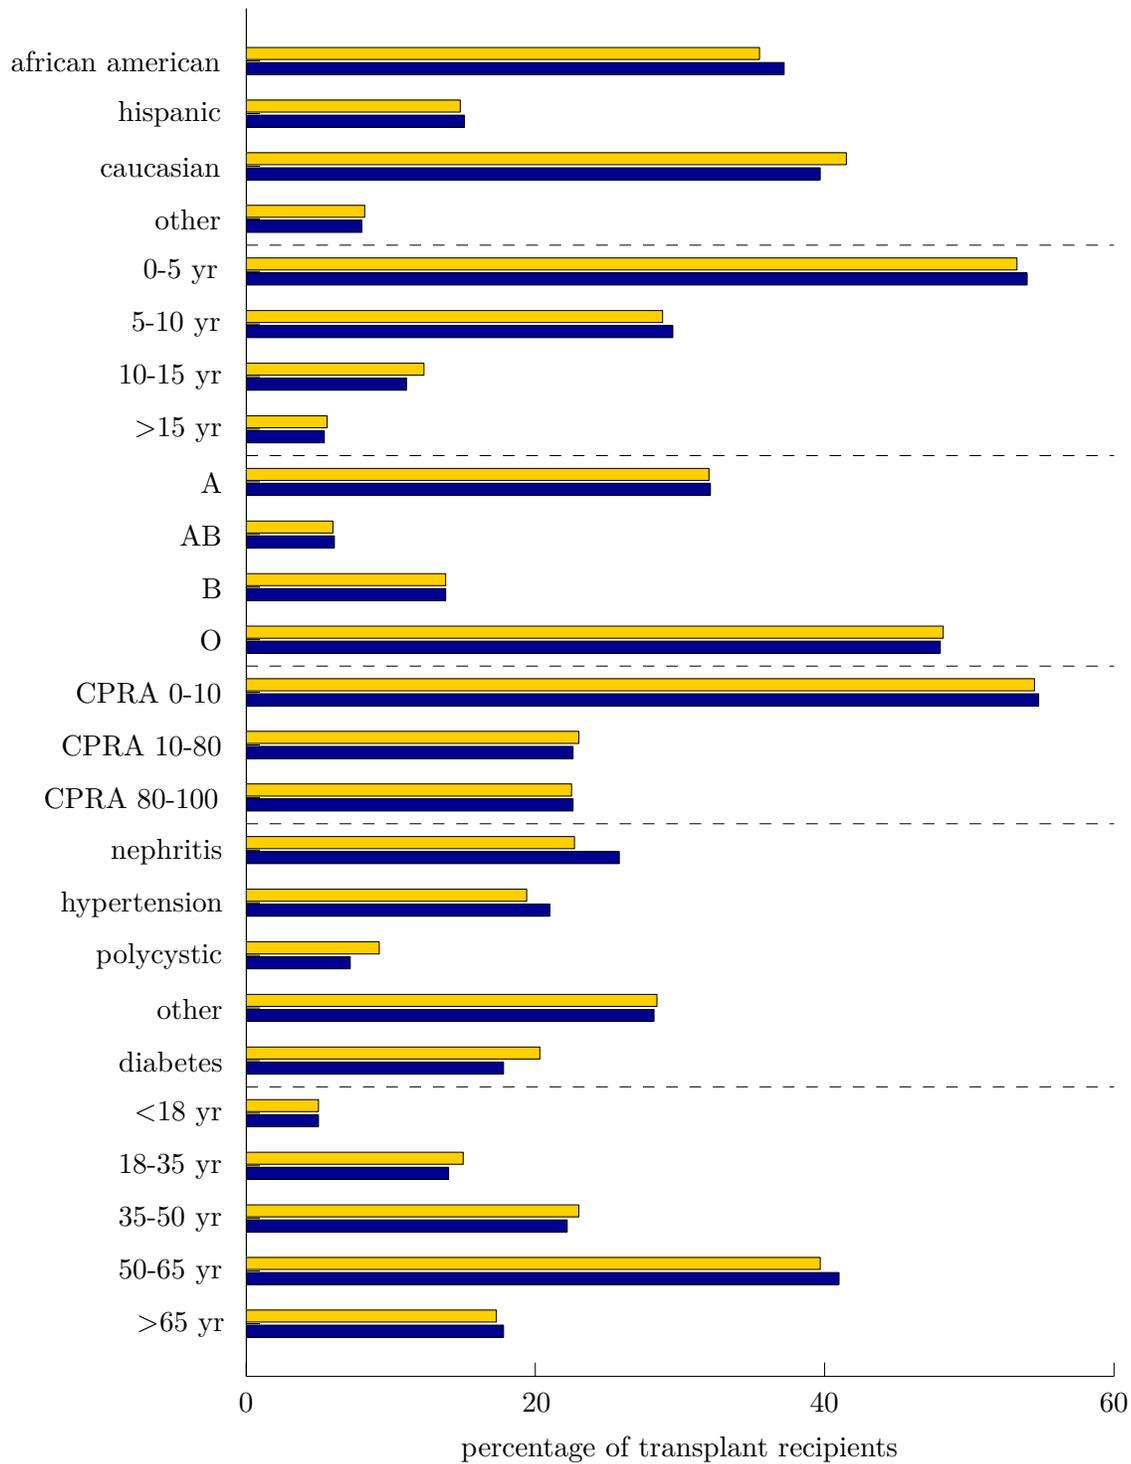

$$\text{KAS}(p, o) = \text{LYFT}(p, o) + h(\text{DT}(p)) + 0.12 \text{CPRA}(p) + 2.5 \mathbf{I}(\text{AGE}(p) \geq 50) + \mathbf{I}(\text{AGE}(p) \geq 65),$$

where

$$h(\text{DT}) = \begin{cases} 0.75 \text{DT}, & 0 \leq \text{DT} \leq 5, \\ \text{DT} - 1.25, & 5 \leq \text{DT} \leq 10, \\ 0.5 \text{DT} + 3.75, & 10 \leq \text{DT}. \end{cases}$$

The simulation results are reported in Table 2 and Figure 4. Sample standard deviations for the percentage distributions are included in the Appendix.

**Discussion.** This case study, alongside the next one, illustrates how our method deals with alternative fairness constraints. In particular, we consider the same setup as in Case Study 2,

**Figure 4:** Simulated average percentage distributions of recipients across different race, dialysis time, blood type, sensitization, diagnosis and age patient groups for the policy designed in Section 4.5, *i.e.*, in case study 3 (yellow). The target distributions are also depicted (blue). The results are for an out-of-sample period of 6 months in 2008.

but introduce a change in the required age percentage distribution of recipients. Our method successfully redesigns a conforming policy.

The change in the age distribution we consider is motivated by comments made by a UNOS Ethics Committee in OPTNKTC (2008). Based on the fact that, in comparison with current practice, the new KTC policy would direct a higher number of organs, or organs of higher quality, to younger patients, the committee argued that the KTC policy might have an unintended consequence of a decrease in living donor transplants for younger patients, who typically have higher LYFT scores. In response to that, in this case study we design a policy that has a more balanced age distribution, which actually resembles the age distribution of patients in the waitlist. Perhaps this consideration is just only one plausible way of addressing the concern raised by the committee. Nevertheless, it is presented here only to illustrate the flexibility of our method, rather than tackle this particular issue.

Finally, note that in comparison with the KTC policy our policy allocates more organs to elder patients, a fact that could significantly undermine efficiency. However, both policies deliver almost identical life year gains (see Table 2), which again illustrates that our method is capable of designing efficient policies.

#### 4.6. Case Study 4

In our final case study we demonstrate how our method can be used to perform a sensitivity analysis with respect to imposed fairness constraints. Specifically, we explore the dependence of life years from transplant gains on the priority given for dialysis time and sensitization.

To this end, we consider a similar setup as in Case Study 2, but we relax the constraints pertaining to patient groups of different dialysis time, *i.e.*, constraints (3), as well as to patient groups of different sensitization level. The relaxation is controlled by a slack parameter. We then study the dependence of life year gains on that parameter.

**Score components.** As in Case Study 2, we use LYFT, a piece-wise linear function of DT (with break points at 5 and 10 years), CPRA and a step-wise function of patient age (with break points at 50 and 65 years).

**Fairness constraints.** We use the same fairness properties with the dominant KTC policy, but we first relax only the constraints pertaining to dialysis time. The relaxation is performed by

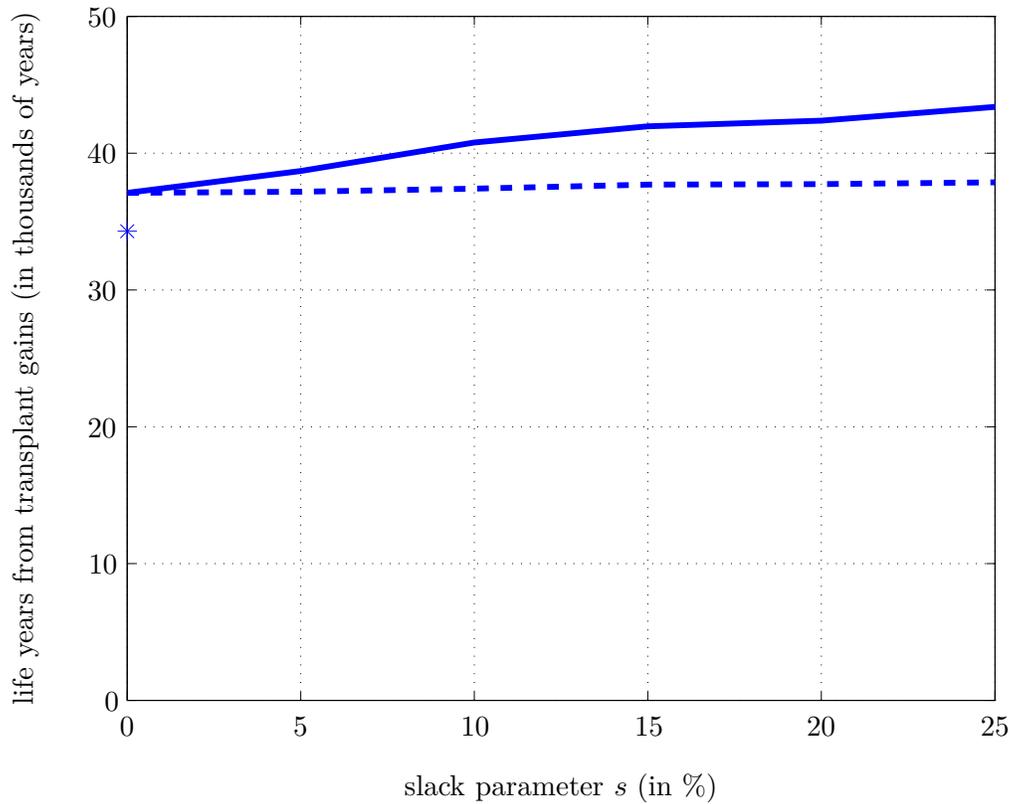

introducing a slack parameter  $s$  in the percentage requirements of recipients of different groups, that is, the relaxed constraints take the form

$$\begin{aligned}
\sum_{p: 0 \leq \text{DT}(p) \leq 5} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} &\geq \frac{54-s}{100} \sum_{(p,o) \in \mathcal{C}} x_{(p,o)}, \\
\sum_{p: 5 \leq \text{DT}(p) \leq 10} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} &\geq \frac{29.5-s}{100} \sum_{(p,o) \in \mathcal{C}} x_{(p,o)}, \\
\sum_{p: 10 \leq \text{DT}(p) \leq 15} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} &\geq \frac{11.1-s}{100} \sum_{(p,o) \in \mathcal{C}} x_{(p,o)}, \\
\sum_{p: \text{DT}(p) \geq 15} \sum_{o: (p,o) \in \mathcal{C}} x_{(p,o)} &\geq \frac{5.4-s}{100} \sum_{(p,o) \in \mathcal{C}} x_{(p,o)}.
\end{aligned} \tag{4}$$

Clearly, for  $s = 0$  one would recover the policy that was designed in Case Study 2. For  $s > 0$ , the requirement on matching the percentage distribution (with regard to patient groups of different dialysis time) achieved by the KTC policy is relaxed. Thus one should expect that policies designed with such relaxed requirements would achieve higher life years from transplant gains. Using our method, we design policies for various values of the slack parameter  $s$  and quantify how the gains in medical efficiency depend on deviations from the selected fairness constraints. Secondly, we follow the same procedure to examine the dependence of medical efficiency on the priority given to sensitized patients. We again use all the constraints as in Case Study 2, but this time relax only the constraints pertaining to patient groups of different sensitization levels. The relaxation is again performed using a slack parameter  $s$ . Note that one can potentially perform a sensitivity analysis through many other different ways of relaxing the constraints; for illustration purposes we focus here only on the described method of uniformly relaxing the constraints by a slack parameter.

**Results.** The results we obtain in the aforementioned scenarios are depicted in Figure 5. The figure shows the life years from transplant gains (for the 6 month period we consider) of policies designed with relaxed constraints on patient groups of different dialysis time or sensitization, for various values of the slack parameter  $s$ . The figures also depicts the operational point of the KTC policy, that is for  $s = 0$ .

**Discussion.** Comparing the two scenarios we considered, one can observe that the dependence of medical efficiency is stronger on dialysis time. Also, the life years from transplant gains can be as high as 44,300 years, which are 30% larger than the gains of the KTC policy. Note that although such a policy might not be implementable, the analysis can provide insights to policymakers and

**Figure 5:** Simulated life years from transplant gains for policies (designed by our method) with relaxed constraints on all patient groups of different dialysis time (solid) or sensitization (dashed), for various values of the slack parameter  $s$ ; for more details see Section 4.6. The results are for an out-of-sample period of 6 months in 2008. The marker corresponds to the operational point of the policy proposed by the UNOS policymakers.

facilitate their decision process.

Nevertheless, this case study illustrates how our method can be used to perform a trade-off analysis that could assist policymakers in quantifying the impact of certain fairness requirements.

## 5. Discussion and Future Directions

We dealt with the important problem of allocating deceased donor kidneys to waitlisted patients, in a fair and efficient way. We focused on national allocation policies in the United States and the recent effort to revise the current policy in place.

Particularly, we studied allocation policies that are based on point systems; under those policies patients are awarded points according to some priority criteria, and patients are then prioritized by the number of points awarded. We identified the challenges in designing a point system, specifically the relative emphasis put on each criterion such that the resulting policy strikes the right balance between efficiency and fairness.

Our main contribution was a scalable, data-driven method of designing point system based allocation policies in an efficient and systematic way. The method does not presume any particular fairness scheme, or priority criterion. Instead, it offers the flexibility to the designer to select his desired fairness constraints and criteria under which patients are awarded points. Our method then balances the criteria and extracts a near-optimal point system policy, in the sense that the policy outcomes yield approximately the maximum number of life years gains (medical efficiency), while satisfying the fairness constraints.

To validate our method and demonstrate its usefulness, we presented 4 case studies in which we designed new policies under different scenarios. In one of them, we designed a new policy that matches in fairness properties the one that was recently proposed by the U.S. policymakers, while being based on a format and criteria already considered by policymakers. Critically, our policy delivers an 8% relative increase in life years gains. The performance gain was established via simulation, utilizing the same statistical tools and data as the U.S. policymakers.

Finally, we presented a trade-off analysis that revealed the dependence of medical efficiency on the important fairness concepts of prioritizing patients who have either spent a lot of time waiting, or are medically incompatible with the majority of donors.

As a pointer for future work, consider the policies that OPTN policymakers have proposed in

which patients and/or organs are categorized into different groups according to some criteria and then specific groups receive priority in the allocation, see Section 2.1. For instance, a proposal presented in OPTNKTC (2007) suggests to categorize patients in 5 different groups according to their expected life year gains: top 20% goes to the first group, bottom 20% goes to the last group, etc. Similarly, organs are categorized according to their quality (DPI). In the allocation then, group 1 patients are given priority for group 1 organs, groups 2 patients are given priority for group 2 organs and so on. Ranking within those groups is again achieved via a scoring rule, so our model would again be applicable and useful. Another interesting question however is, how can should one decide on the “right” categorization? In the example we gave, how does one exactly partition patients into those 5 groups? As an extension and future work, one can potentially use modified versions of our framework to guide such decisions. We present a related case study in the Appendix.

## Appendix

### A. Simulation Results

Table 3 includes the simulated average percentage distributions (and sample deviations) of recipients across different race, dialysis time, blood type, sensitization, diagnosis and age patient groups for the policies designed in the case studies in Section 4, alongside the KTC proposed policy. The results are for an out-of-sample period of 6 months in 2008.

### B. Category-based Policies

As discussed in Section 5, OPTN policymakers have proposed policies in which patients and/or organs are categorized into different groups according to some criteria. Then, specific groups receive priority in the allocation of kidneys. For instance, a proposal presented in OPTNKTC (2007) suggests to categorize patients in 5 different groups according to their expected life year gains (LYFT): top 20% goes to the first group, bottom 20% goes to the last group, etc. Similarly, organs are categorized according to their quality (DPI). In the allocation then, group 1 patients are given priority for group 1 organs, groups 2 patients are given priority for group 2 organs and so on. In this section we illustrate how one can use a modified version of the framework developed in Section 3 to decide how one should partition patients and/or organs to such groups.

Suppose we want to design a policy that categorizes patients and organs into groups A and B, according to their (average) LYFT and DPI scores. Specifically, the top  $q\%$  of patients are categorized into group A and the remaining into group B, where  $q$  is a policy parameter that needs to be determined. Similarly we categorize the top  $q\%$  of organs into group A and the remaining into group B. Then, once an organ of group A is procured, patients from group A have priority over group B patients. Patients are then ranked by the time they have spent on dialysis (DT).

If  $q = 0$ , the allocation policy is essentially a first-come first-serve policy (FCFS), with respect to dialysis time. As  $q$  increases and we depart from a pure FCFS policy, more emphasis is given to efficiency as high quality organs are first offered to patients who are likely to benefit more from them (in terms of life year gains). Thus, one expects higher LYFT gains. As  $q$  approaches 100 however, we again recover FCFS. Below we discuss a way of guiding the selection of  $q$  based on our

**Table 3:** Simulated average percentage distributions (and sample deviations) of recipients across different race, dialysis time, blood type, sensitization, diagnosis and age patient groups for the policies considered in Section 4, for an out-of-sample period of 6 months in 2008.

framework.

For the case of FCFS, *i.e.*,  $q = 0$  or  $q = 100$ , one can solve problem (1) without any fairness constraints and with objective coefficients equal to  $DT(p)$  for every  $(p, o)$  pair, to obtain an “approximate” expected allocation. Suppose we now consider  $0 < q < 100$ . Let  $A_P(q)$  and  $A_O(q)$  be the sets of all group A patients and organs respectively. We then define an adjusted set of eligible patient-organ pairs  $\mathcal{C}(q)$  (see Section 3.1), in which group A organs are only allocated to group A patients (according to the selected value of  $q$ ), *i.e.*,

$$\mathcal{C}(q) = \{(p, o) : (p, o) \in \mathcal{C} \text{ and } p \in A_P(q) \text{ if } o \in A_O(q)\}.$$

One can then solve the following problem to obtain an “approximate” expected allocation for any selection of  $q$ :

$$\begin{aligned} & \text{maximize} && \sum_{(p,o) \in \mathcal{C}(q)} DT(p)x_{(p,o)} \\ & \text{subject to} && \sum_{o:(p,o) \in \mathcal{C}(q)} x_{(p,o)} \leq 1, \quad \forall p \\ & && \sum_{p:(p,o) \in \mathcal{C}(q)} x_{(p,o)} \leq 1, \quad \forall o \\ & && x \geq 0. \end{aligned} \tag{5}$$

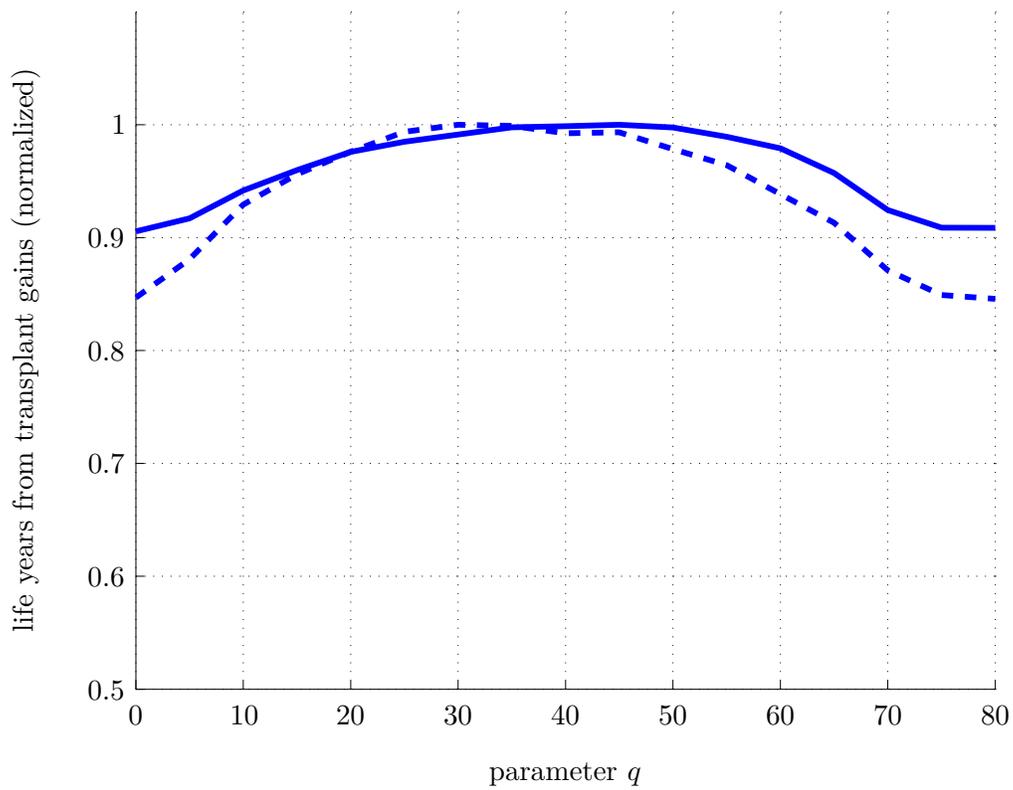

Let  $x(q)$  denote an optimal solution of (5) for any selection of  $q$ .

To quantitatively characterize the efficiency of each of those policies (as we vary  $q$ ), one can calculate the quantity

$$\sum_{(p,o) \in \mathcal{C}(q)} LYFT(p, o)x_{(p,o)}.$$

In some sense, the above quantity is associated with the anticipated life year gains in case organs are allocated using such a policy. Figure 6 depicts the (normalized) values we obtain for the anticipated life year gains for different values of  $q$ , by using our training data of the 2008 SRTR dataset (see Section 4.2). Such a graph can be used by policymakers to decide on the value of  $q$ , as it characterizes which values are expected to provide high life year gains.

To evaluate the performance of the method we described, we use the out-of-sample 6 month data of the 2008 dataset to simulate policies for various values of  $q$ . For each value of  $q$ , we record the number of life year gains. The (normalized) results are depicted in Figure 6. One can observe that

**Figure 6:** Predicted (solid) and simulated (dashed) life years from transplant gains for different values of the parameter  $q$  for the case study in Section B.

points per year on dialysis 10-15	0.1	0.15	0.2
points per year cpra score	0.08	0.08	0.08
points if aged above 50	0.5	0.5	0.5

**Table 4:** Simulation results for the KTC policy and policies designed as in Case Study 2 in Section 4.4, for different planning horizons; see Section C.

	KTC policy	3 months	4.5 months	6 months
organ wastage (std)	14.6% (0.3%)	22.2% (0.4%)	15% (0.3%)	14.5% (0.3%)
avg lyft (std)	5.9 (0.03)	6.48 (0.06)	6.38 (0.04)	6.35 (0.04)

**Table 5:** Simulation results for the KTC policy and policies designed as in Case Study 2 in Section 4.4, for different planning horizons; see Section C.

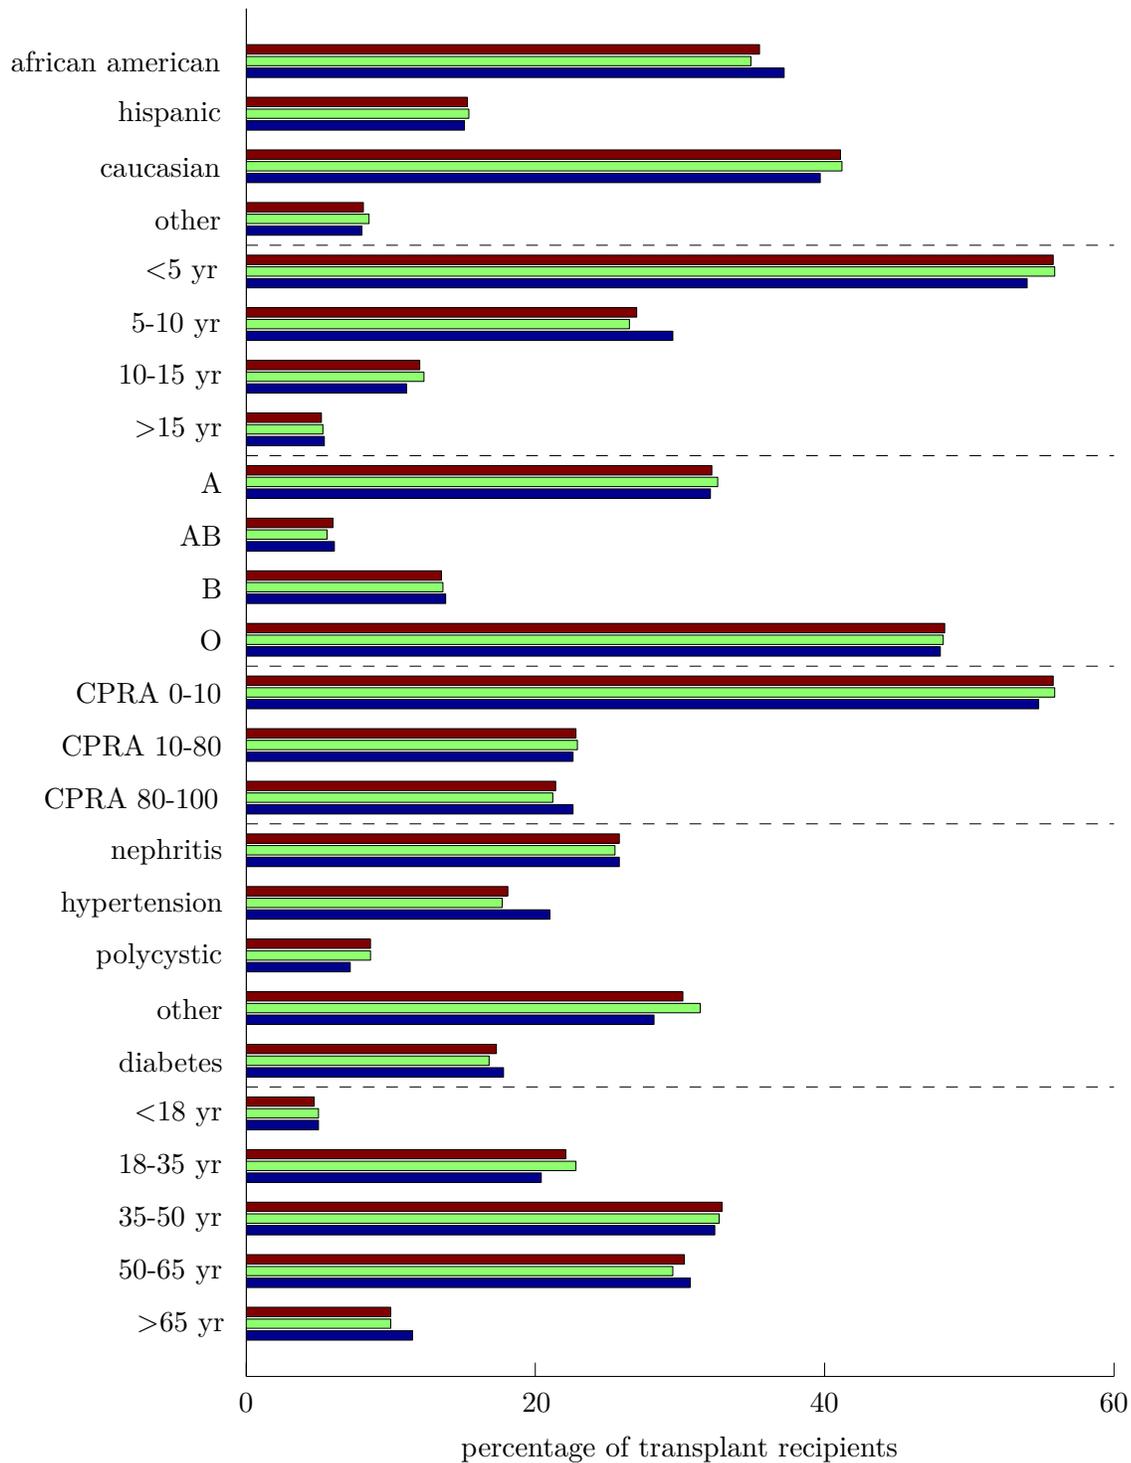

our methodology accurately predicts the qualitative dependence of life year gains on the parameter  $q$ .

Finally, note that in a realistic setting, points would also be given to patients not just based on their dialysis or waiting time, but also based on sensitization and perhaps other criteria, so as to enforce particular fairness constraints. In that case, one can modify the methodology described above to include those fairness constraints in Problem (5).

## C. Additional Case Studies

In this section, we repeat Case Study 2 (see Section 4.4) for different planning horizons. In particular, in Case Study 2 we considered a planning horizon of 6 months (primarily because of data availability). To study the effect of the length of the planning horizon, we present here results for planning horizons of 3 months and 4.5 months.

Table 4 reports the weights that our methodology assigns to each of the score components of the policy, for the different planning horizons we consider. Similarly, Table 5 reports the average organ wastage, *i.e.*, the percentage of procured organs that were discarded due to successive rejections by patients, and the average life years from transplant. Finally, the distributions of recipients among different groups are depicted in Figure 7 and reported in Table 6.

**Figure 7:** Simulated average percentage distributions of recipients across different race, dialysis time, blood type, sensitization, diagnosis and age patient groups for the policies designed in Section C, for different planning horizons: 3 months (green) and 4.5 months (red). The target distributions of the KTC policy are also depicted (blue). The results are for out-of-sample periods of 3 (or 4.5) months in 2008.

	KTC		3 months		4.5 months	
	mean	std	mean	std	mean	std
<b>race</b>						
african-american	37.2	0.45	34.9	0.75	35.5	0.5
