Abstract

In 2020, gamers worldwide spent more than $15 billion on loot boxes, a lottery of virtual items built into video games. Loot boxes are contentious, as regulators worry that they constitute gambling. In contrast, video game companies maintain that loot boxes are complementary to gameplay. Using data from a mobile puzzle game, we separate out alternative mechanisms behind tastes for loot boxes. We find that the sources of value of loot boxes differ dramatically between “whales,” 1.5% of players responsible for 90% of the game’s revenues, for whom only 3% of loot box utility comes from gameplay complementarity, and everyone else who open loot boxes mainly (90% of utility) for in-game value. We leverage taste estimates to evaluate product (game and loot box) design counterfactuals, showing how the company trades-off revenue from whales and engagement with the game from non-whales. We measure the welfare effects of three policy actions – a blanket ban on loot boxes, a ban on paid loot boxes, and limit-setting on the players’ expenditures. We find that a debated policy option, a blanket ban on loot boxes, hurts consumers by removing the gameplay complementarity that players derive from loot boxes, and we present evidence in favor of spending caps.

1 Introduction

Around 3 billion people around the world – and two-thirds of Americans – played video games in 2021 [Newzoo, 2021, ESA, 2022]. Monetization of this estimated $160 billion market heavily relies on loot boxes, an in-game lottery of virtual items, which generated more than $15 billion of revenue for gaming companies in 2020 [Juniper Research, 2021, Statista, 2021], and is projected to only further increase in importance for the industry.

Loot boxes are contentious. On the one hand, the industry argues that loot boxes are purely optional, enhance gameplay, and improve players’ performance [e.g. ESA, 2019]. They are complementary features of the overall game. On the other hand, some regulators and consumer protection groups argue that repeatedly paying for and opening loot boxes closely resemble gambling. Players get the thrill from revealing the uncertainty of loot box outcomes, both due to the entertainment value [e.g. Ely et al., 2015] and behavioral biases like self-control problems [e.g. DellaVigna and Malmendier, 2006]. Such impulsive consumption can lead to “overspending” that has negative financial, behavioral, and health consequences. High spenders may have gambling problems [e.g. Zendle et al., 2019, Close et al., 2021] and many consumers are minors, who are most susceptible to developing problematic habits [e.g. Kristiansen and Severin, 2020]. The controversy around loot boxes is evident in how varied the regulatory response has been across jurisdictions: while some countries regulate them (e.g. Belgium, China), others have decided not to (e.g. New Zealand, Poland) or to continue investigating them (e.g. US, UK).

We develop an economic framework to analyze and separate out two sets of tastes for loot boxes. The first set of tastes is the expected gameplay value of the items consumers might receive from loot boxes: items help make progress in the game. This is the functional value of loot boxes. This mechanism maps on to the arguments of gaming companies who argue that loot boxes are complementary to gameplay, and thus should not be regulated because they are part of a larger “game of skill” (in which higher-skilled players are more likely to win). The second set of drivers is the direct thrill utility that consumers get from opening loot boxes. These drivers include both normatively respectable preferences – like entertainment value from the resolution of uncertainty [e.g. Ely et al., 2015] – and drivers arising from behavioral biases like self-control problems and cue-based consumption [Lockwood et al., 2021], often triggered by the design of loot boxes that builds anticipation for rewards [Close and Lloyd, 2021]. This mechanism suggests that players see the thrill in loot boxes themselves, making them a stand-alone “game of chance,” in which skill plays a limited role.

The distinction between these two sources of tastes matters both legally and economically.
Whether the game is a “game of chance” or a “game of skill” is one of the key factors that define a game as a gamble, a legal criterion called the predominance test [e.g. lexology.com 2018]. The nature of players’ tastes for loot boxes affects the source of surplus that consumers derive from the game overall and informs policy proposals, such as a ban on loot boxes and spending caps.

We estimate players’ tastes for loot boxes in a case study of a free-to-play puzzle game – for which we have full transaction and activity data – to understand why players open loot boxes. Users play to complete sequential game “stages” of increasing difficulty. To make progress in the game, they increasingly need more potent virtual characters. These rarer characters can be collected by opening loot boxes using in-game or real currency. Users acquire the in-game currency by playing the game. Users accumulate inventories of these virtual characters and select the best ones to play game stages. We observe the universe of data from this game, including full records of 2.5 million users’ decisions to play, open loot boxes, and spend money, as well as their character inventory, in-game currency stock, and realizations of loot boxes. Loot boxes are used heavily: players open around 20 million paid loot boxes, and 96% of the companies’ in-game revenues come from loot box openings.

This rich transaction and activity data provide a unique context to separately identify mechanisms behind players’ tastes, by leveraging the timing of players’ loot box openings. If the functional value plays a role in players’ decisions, users should be more likely to open loot boxes when loot box items have a higher incremental effect on game win probabilities. We leverage gameplay data to estimate the incremental effect of “good” and “bad” loot box outcomes (diers with higher and lower rarity) on win probabilities across a variety of inventory states. Comparable players end up in different inventory states due to the randomness of both previous loot boxes and gameplay outcomes. We use this exogenous variation in states to separately identify how much functional value players get from loot boxes, by comparing changes in play and loot box opening probabilities across states with varying returns to opening loot boxes.

We first characterize users’ tastes in a series of reduced-form regressions. Players are more likely to open a loot box after losing the stage due to a particularly hard realization of stage complexity, suggesting a distaste for losing the game. Yet, over the arc of the game, the propensity at which users open loot boxes is relatively constant. This is despite the fact that once obtained, characters do not decrease in their effectiveness, and loot boxes deliver nearly two orders of magnitude higher functional benefits early on in the game. Such behavior is more consistent with the presence of direct utility, and data suggest that impulsive consumption plays a prominent role in it – 66% of loot boxes are opened almost instantaneously after another loot box. The median time between such sequential openings is only 19 seconds, roughly the length of time it takes to complete the operation of opening a loot box.

The expenditures are highly concentrated across users, with 90% of revenue coming from 1.5% of players. Such high-spending players are referred to as “whales” in the industry. We leverage the randomness of loot box outcomes and show the drastically different nature of tastes for loot boxes of whales and non-whales. Non-whales sharply increase their stage play propensity when they receive rare items from loot boxes. In contrast, the response of whales is tiny and not distinguishable from zero if they have a relatively strong inventory. Instead, reduced-form estimates suggest that whales open loot boxes for their direct value. State dependence in loot
box openings – a proxy for impulsive consumption – plays a prominent role in whales’ tastes.

Informed by these data features, we build and estimate an empirical model of gameplay and loot box choices that is grounded in our framework. A consumer chooses between playing the game, opening loot boxes, or leaving the game forever in a series of discrete choices given her current inventory, game stage, and currency stock, among other factors. The consumer gets utility from playing the stage regardless of the outcome and additional utility from “winning,” i.e. advancing a stage. A consumer is more likely to win if she holds a better inventory of items. Thus, in expectation opening a loot box improves future utility flow by adding a good character to her inventory, capturing the functional value of loot boxes. At the same time, the consumer can get direct thrill utility from opening loot boxes. To open loot boxes, a consumer needs to spend in-game currency, which can be acquired by playing the game more or paying with real money. Thus, the variation in players’ currency stock introduces a dynamic trade-off between opening loot boxes and playing the game, and pins down the price responsiveness of players. We proxy for impulsive openings of loot boxes with a first-order Markov state dependence variable. This captures an upper bound on the thrill value associated with players’ lack of self-control.

We estimate the dynamic discrete choice model using a two-step procedure [Hotz and Miller, 1993]. While our state space is large – 4.9 million states – the estimation is simplified because of the existence of a terminal action, leaving the game. Following [Arcidiacono and Miller, 2011], we express the expected value functions as a function of the conditional choice probabilities estimated in the first stage, and estimate utility parameters in the second. We allow for different preferences for whales and non-whales by estimating the model separately. We check the robustness of our estimates by allowing for more heterogeneity in users’ tastes, clustering whales and non-whales based on the players’ stage play propensities [Bonhomme et al., 2022].

The estimates confirm the fundamental difference in tastes for loot boxes of whales and non-whales. Whales have a higher taste for opening loot boxes regardless of their outcomes, and the parameter governing state dependence in loot box openings is around twice as high for whales than non-whales. A utility decomposition exercise enables us to quantify the relative importance of the functional and direct thrill values of loot boxes for players. Our empirical model characterizes loot box openings as largely functional for the majority of players: the functional mechanism accounts for almost 90% of loot boxes’ value for non-whales. In contrast, whales get 97% of loot box value from the direct mechanism, and tastes for state dependence in loot box openings account for around a third of this value.

To understand the complementarity between loot box design and gameplay, we simulate player behavior under alternative scenarios of difficulty of stage games, and of loot box outcomes variability. We show that by making the game harder, i.e. decreasing win probabilities across stages, the gaming company can extract more revenue from whales. Yet in doing so it substantially loses the engagement of non-whales. Gaming companies often value the engagement of non-whales, as their engagement can generate positive direct network effects. Changing the variability of loot box outcomes has a substantially lower impact on revenues and players’ behavior; our results suggest that the firm can be slightly better off if it decreases the variance of item rarity that players receive from loot boxes.

We conclude by measuring the welfare effects of various policy actions proposed by consumer
protection groups and regulators. In a series of counterfactual simulations, we show that a blank-
et ban on loot boxes [e.g. like the one discussed by ForbrukerRådet 2022] is too stringent as a
policy action. For most players – more than 98% of non-whales – there is a strong complement-
tarity between the game and loot boxes, and a full ban would reduce consumer surplus from
playing the game itself by 23.2%. On the other hand, whales maintain the same surplus from
playing the game since for them the core value of loot boxes is not the complementarity with the
puzzle game but a direct thrill value. Around two-thirds of the thrill value is captured by state
dependence in loot box openings, a proxy for impulsive consumption. Simulations show that
spending caps recover the vast majority of the functional value of loot boxes (since non-whales
are not affected) while preventing the firm from profiting off of overspenders. Thus, our results
support the proposals of Close and Lloyd 2021 and Leahy 2022, who advocate for actions like
spending caps, pre-committed limits, and forced breaks from opening loot boxes.

Our paper contributes to several streams of literature. First and foremost, we contribute
to the growing body of work on loot boxes in social sciences and engineering [e.g. King and
2020, Xiao 2021]. While most work relies on interviews, surveys, and correlational analysis
to understand the value of loot boxes for players [e.g. Zendle et al. 2019, Close and Lloyd
2021, Spicer et al. 2022], we are the first to provide a revealed preference measure of players’
tastes. We also bring in unique field data, evaluate alternative product designs, and measure the
welfare effects of various policy actions. The decomposition of the thrill value of loot boxes into
the normatively respectable entertainment component and openings driven by behavioral biases
build on the conceptual framework in Lockwood et al. 2021. Our evaluations of counterfactual
game designs contribute to the emerging literature on product design in the gaming market
[e.g. Nevskaya and Albuquerque 2012, Sunada 2018, Ishihara and Ching 2019, Huang et al.
2019, Zhao et al. 2022], as well as the broader media and entertainment markets [e.g. Crawford
and Yurukoglu 2012, Fan 2013, Sweeting 2013, Jezierski 2014, Martin and Yurukoglu 2017,
Cagé 2020, Liu et al. 2020, Kaplan 2021, Simonov et al. 2022]. Our estimates of players’
tastes for loot boxes add to the empirical literature on gambling [e.g. Jullien and Salanié 2000,
Narayanan and Manchanda 2012, Park and Manchanda 2015, Taylor and Bodapati 2017, Park
and Paneras 2022] and self-control problems in media consumption [e.g. Acland and Chow 2018,
Hoong 2021, Allcott et al. 2022, Aridor 2022]. Methodologically, we extend the domain of
estimations of single-agent dynamic models with a finite dependence property [e.g. Arcidiacono

The rest of the paper is organized as follows. In Section 2, we describe the institutional
context surrounding loot boxes. Section 3 fixes ideas using a toy model that highlights the dual
mechanism of value behind loot boxes. Section 4 describes the focal video game and our data.
In Section 5, we build a structural model of gameplay and loot box openings. Section 6 presents
model-free evidence that supports the two mechanisms behind consumers’ tastes for loot boxes
in our empirical context. Section 7 discusses the estimation procedure, and Section 8 presents
the resulting estimates. Leveraging counterfactual simulations, in Section 9, we evaluate the
implications of game and loot box design for the firm’s revenue and game engagement. We
conclude and discuss policy implications in Section 10.
2 Institutional Context

2.1 Video Game Companies’ View

The video game industry has rapidly expanded in recent years. In 2020, the industry was worth an estimated $159.3 billion – a 126% increase compared to the $70.6 billion value in 2012 [Statista 2021], outgrowing the movie and music industries combined [Investopedia 2021]. With three billion video game players choosing from more than one million games to play, competition is fierce [remarkablecoder.com 2019]. This competition, along with advances in technology, has led to an exponential increase in the costs of producing high-quality video games [1]. However, due to competitive pressure, the list prices of major video games have remained at the same level (around $60) for the last 15 years [extremetech.com 2020]. These unfavorable economics have led video game companies to search for other monetization methods to cover costs and to fund future products.

One type of such new monetization methods are in-game purchases, commonly referred to as microtransactions. Microtransactions allow users to purchase virtual items within the game, enhancing the gaming experience, and are omnipresent in both free-to-play (or “freemium”) games and major titles. Driven by microtransactions, in 2018 the market for free-to-play games grew to $88 billion worldwide [techcrunch.com 2019].

One of the most common types of microtransactions is a “loot box.” Players purchase a “black box” from which they obtain a randomized selection of virtual items to be used in subsequent gameplay. Apart from subsidizing the list price of the game in a form of “razor and blades” pricing, loot boxes allow companies to exercise price discrimination in other ways, such as bundling (bundling different items together in a loot box) and volume-based pricing (providing a discount for opening multiple loot boxes at the same time).

Loot boxes also have benefits for players. They allow players to get in-game items that make the game more enjoyable, either by enhancing in-game skills, or by making the game more visually appealing and personalized. The uncertainty over the quality of the items that players receive in loot boxes also has a potential benefit. If making progress in the game requires a big boost in in-game performance, there is an economic argument for why it might be optimal for players to take a lottery for a chance at obtaining a high-quality item, that will allow them to advance faster [2]. A statement by the Entertainment Software Association, the trade association for the U.S. video game industry, captures this line of argument well: “Loot boxes are a voluntary feature in certain video games that provide players with another way to obtain virtual items that can be used to enhance their in-game experiences” [gameinformer.com 2018].

2.2 Regulators’ View

While loot boxes have become instrumental for video game companies to generate revenues, they have also received attention from regulators, who often have a less favorable view of the practice. Loot boxes share many features with gambling, which is regulated in most countries.

---

1. Major titles can cost hundreds of millions of dollars to produce, e.g. see gamedeveloper.com 2018.
2. This argument is akin to the indivisibility of expenditures argument in explaining the demand for lotteries, especially in low-income areas [Kwang 1965, Rosen 1997].
When opening loot boxes, players receive a randomized selection of items, suggesting that players potentially get a similar direct utility from uncertainty as they would when gambling, for instance, in casinos [Zendle et al., 2019]. This similarity between loot boxes and other gambling contexts suggests that issues associated with problem gambling, such as addiction, cue-based consumption, and the resulting overspending, may also be associated with loot boxes. Rare loot box outcomes give players similar psychological arousal and rewards as slot machines [Larche et al., 2021]. These concerns are particularly pronounced since many players are minors [e.g. Kristiansen and Severin, 2020], who are prohibited from gambling in many jurisdictions.

The controversy around loot boxes is evident in how varied the regulatory response has been across jurisdictions. Some countries have chosen to classify loot boxes as gambling and to regulate or ban them. For instance, the Netherlands has banned some loot boxes, and Belgium has banned all loot boxes, arguing that these are games of chance [screenrant.com, 2018]. China has requested game producers to disclose the probabilities of items received from loot boxes [gamedeveloper.com, 2016]. In contrast, New Zealand and Poland have declared that loot boxes do not constitute gambling [e.g. gamedeveloper.com, 2017]. A number of countries are still investigating the nature of loot boxes, including a call for evidence in the United Kingdom in 2020 [gov.uk, 2022] and a 2019 public workshop on loot boxes by the Federal Trade Commission in the United States [Federal Trade Commission, 2020].

A core element of this debate concerns the role of “chance” that loot boxes add to the overall game. While the legal definitions of gambling vary across jurisdictions, a key factor in defining a game as a gamble is whether the game can be considered a “game of chance” (in which skill plays a limited role) rather than a “game of skill” (in which higher-skilled players are more likely to win). A commonly used legal test is the predominance test, which places games on a scale between a complete game of chance (e.g. rolling a dice) and a complete game of skill (e.g. playing chess). While the loot box in itself constitutes a “game of chance” – since loot box outcomes are completely random – views vary on the role that loot boxes play in the overall gameplay experience. For instance, a 2022 ruling by the Dutch Administrative Jurisdiction Division overturned a previous court ruling that loot boxes in a popular video game constituted gambling [Dutch Council of State, 2022]. Instead, the Division stated that the loot boxes played a functional role in an overall game of skill, and the loot boxes could not be evaluated as an isolated product. The Division, therefore, highlighted the presence of complementarities between loot boxes and gameplay in its ruling.

---

3 Some evidence suggests that players themselves liken the activity to gambling [pcgamer.com, 2017]. Zendle et al. [2019, 2020] show there is a correlation between opening loot boxes and future problem gambling behavior, and the United Kingdom’s National Health Service argued in 2020 that loot boxes lead to gambling addiction among minors [NHS, 2020]. A study by the Netherlands’ gaming authority has argued that loot boxes “have integral elements that are similar to slot machines,” including a “near miss” effect of almost winning something and visual cues, among other things [pcgamer.com, 2018].

5 Most jurisdictions that allow gambling require people to be 18 years old or older to be allowed to gamble [casino.org, 2020].

6 Another important argument is whether the items received from loot boxes are items of “value,” monetary or otherwise. For a succinct discussion of the legality of loot boxes, see [jdsupra.com, 2019].

7 For a short summary see [lexology.com, 2018]. States and countries have adopted different thresholds for what constitutes a game of skill versus chance and might disagree. For instance, New York state deems poker a game of skill, while other states have deemed it a game of chance [New York Times, 2012].
2.3 This Paper’s View

We build on the video game companies’ and regulators’ arguments to provide a revealed preference, utility-based framework that captures the functional value of loot boxes – allowing players to receive virtual items that complement gameplay – and a direct utility of opening loot boxes as a gamble, including the thrill of the opening experience and impulsive consumption.

In our framework, the functional and thrill values of loot boxes can be thought of as two extremes. At one end of the spectrum, we have consumers who open loot boxes primarily for their functional value – e.g. to make progress in the game, as argued by the video game companies. For such players, the loot box is an integral part of the game. For these players, loot boxes should be not regulated as gambling. At the other end of the spectrum, consumers want to open loot boxes regardless of the state of the game or their current inventory. They seek to get the thrill of variable rewards “dropping” from the loot box, capturing both the normatively relevant tastes and behavioral biases. For these players, loot boxes are a pure gambling-like product, which may justify regulation, with the latter source of tastes driving problem gambling [Lockwood et al., 2021].

In reality, players might be getting both functional and thrill value from loot boxes. Whether the regulator will want to consider them gambling and regulate them depends on the relative importance of each mechanism. In this sense, our framework maps well onto the aforementioned predominance test, in which a game is considered a game of chance if randomness is “more important” for winning in the game than skill. In our case, consumers getting the thrill of uncertainty from loot boxes is akin to them engaging in a pure “game of chance.” In contrast, consumers getting functional value from loot boxes is akin to them playing an overall “game of skill.” In the next section, we formalize our framework and build a model that teases apart the functional and direct value that consumers receive from loot boxes.

3 A Toy Model

Building on the contrasting views between the video game companies and regulators outlined above, we present a simple model of gaming with loot boxes to formalize the arguments.

Consider a static problem of a consumer who makes two discrete choices: whether or not to play the game, \( Y_G = \{0, 1\} \), and whether or not to open a loot box in the game, \( Y_L = \{0, 1\} \).

As is common in games, users extract value from making progress in the game (e.g. by “winning” a stage or “clearing” a puzzle). If a consumer chooses to play \( (Y_G = 1) \) she gets

\[
u(Y_G = 1, Y_L) = \alpha_G + \beta \Pr(\text{win}|Y_L),\]

(1)

where \( \alpha_G \) is a preference for playing the game and \( \beta \) is a preference for winning in the game.

Before playing, the consumer does not know whether she will win and takes an expectation over her odds of winning the game. It is a function of \( Y_L \), the decision to open a loot box. Opening a loot box \( (Y_L = 1) \) can weakly increase the win probability, \( \Pr(\text{win}|1) - \Pr(\text{win}|0) \geq 0 \) – for instance, because opening a loot box gives the player a chance to get a good item that will improve her gameplay in a game of skill.
Apart from the gaming utility, a consumer that opens a loot box \((Y_L = 1)\) gets utility

\[
u(Y_L = 1) = \alpha_L - \gamma p,
\]

where \(\alpha_L\) is the direct utility from the loot box. This may be a “true” normatively respectable preference over the uncertainty or a taste that is driven by misperceptions from behavioral biases. We denote the price of the loot box as \(p\), and \(\gamma\) is the marginal utility of currency. The consumer gets zero utility if she does not play the game and does not open the loot box.

This simple model formalizes the two diverging views between the gaming companies and the regulators. The companies argue that most of the value from loot boxes comes through the functional mechanism, \(Pr(\text{win}|1) - Pr(\text{win}|0)\). The consumer protection groups argue that players open loot boxes for utility associated with the opening of the loot box itself, captured by \(\alpha_L\) in our toy model, which can be driven by the true or misperceived entertainment value of loot boxes.

Our goal is to separate out the relative importance of these two mechanisms. The model illustrates that the decision to open a loot box and to play a game are closely interlinked if loot boxes play a functional role: opening a loot box increases the appeal of playing the game to the extent that the play prefers to win. In other words, the likelihood at which users play the stage game or open a loot box as a function of the difficulty of the game, or the functional benefit of the loot box, helps identify the magnitude of the functional mechanism. We now turn to describing the empirical context and stylized facts from the data.

4 Empirical Context

4.1 Game Description

We focus on a Japanese free-to-play mobile puzzle game that was available from April 2015 till July 2019. Players go through a sequence of 173 stages. In each stage, a grid of colored gemstones is presented. A virtual (computer) enemy and the player take turns “attacking” their opponent, with the player doing it by connecting gemstones of the same color. The player’s “attack” is enhanced by the quality of the characters that the player has picked from her inventory to accompany her in a game stage — having better characters enables the player to attack more effectively. The optics of the game mimic other popular games in the same genre, such as Candy Crush saga. Figure 1a shows an example of one stage that is visually similar to the focal game; enemies are displayed in the top section of the screen, and gemstones are in the middle of the screen.

The goal of the game is to progress through the 173 stages. The players are guided through the “roadmap” of stages, similar to one depicted in Figure 1b. They can proceed to the next stage only after completing the previous stage. As the stages progress, the game generally becomes more difficult, thereby requiring higher player skills and better inventory.

The characters — the main virtual items that players can collect in their inventories — are

\[\text{Electronic copy available at: https://ssrn.com/abstract=4355019}\]
called “divers.” Before playing a stage, players pick divers from their inventory (up to four divers) that they will use to assist in their attacks. The player starts from a limited inventory of divers and gets more divers as the game progresses. There are two primary mechanisms of receiving new divers. Firstly, players can collect and strengthen their characters through organic gameplay, namely by clearing stages, but this requires a substantial investment of time and effort by players. Secondly, at any time players can open loot boxes. Opening a loot box always results in the player obtaining one diver or other items, but the rarity and color – vertical and horizontal attributes of divers – can vary. For instance, the player may receive a diver that is comparable or inferior to a diver that she already has in her inventory. Figure 1 depicts an example of information that is disclosed on a loot box purchase screen. Players observe the probability distribution of possible loot box outcomes before purchasing a loot box.

Purchases in the game are made with virtual currency we will call “coins.” Players can get coins organically, as they make progress in the game – for instance, winning a stage for the first time gives a player one to three coins. Users can also purchase coins with real money. The price of one coin varies from roughly 60 to 120 cents, due to non-linear pricing. For example, 12 coins were frequently available for $8.10.

Players use coins primarily to purchase loot boxes. Loot boxes have a non-linear pricing schedule. One loot box has a regular price of five coins, while a set of 11 loot boxes is commonly 50 coins, a five-coin discount. Players may receive other discounts; the most typical discount is when a user opens a loot box for the first time at specific parts of the game; in this case, one loot box costs 3 coins and 11 loot boxes cost 40.

In this game, apart from loot boxes, there are other microtransactions that players can purchase. For instance, the game allows for buy-ins to continue playing a stage that the user is just about to lose. However, these alternative in-game microtransactions are much less popular — loot boxes account for 96% of in-game expenditures.

### 4.2 Data

We now describe our data, provided by the gaming company and extracted directly from the company’s production databases. The data contains the universe of observations of all player actions, gameplay and loot box realizations, expenditures, and game feature descriptions.

**Play and Loot Box Data.** The most substantial part of our data is the logs of users’ actions. In the gameplay log, the key variables are user ID, stage ID, date and time of playing the game, and an indicator for whether the stage was successfully completed. In the loot box log, the key variables are user ID, date and time of opening a loot box, and the loot box outcome.

There is a total of 2.52 million users who played the game and are recorded in our dataset, who are responsible for a total of 217.9 million play occasions and 49.6 million loot box openings. Out of these, 96.7 million play occasions are of the main stage, and 19.8 million openings are of rare loot boxes. There is an option of purchasing 11 loot boxes at once, for a small volume-based

---

9There are two types of loot boxes in this game. “Rare loot boxes” are paid for using in-game currency (“coins”), while “normal loot boxes” are opened with in-game points. The latter tend to provide divers of low rarity and are less relevant for building up the inventory. Throughout the analysis, we focus on rare loot boxes; from now on, we mean “rare loot boxes” when saying “loot boxes” unless we specify otherwise.
Panel (a) depicts a game stage. Enemies are displayed on the top of the screen. The divers that the player has chosen from her inventory to play this round are displayed at the bottom of the screen. The player “attacks” by connecting gemstones of the same color. The more gemstones are connected, the stronger the divers’ attacks. Panel (b) presents the screen caption of the stages roadmap; players need to complete stage 1 to go to stage 2, stage 2 to go to stage 3, etc. Panel (c) is an example of information displayed before a user purchases a loot box. The screen shows the probabilities of getting a diver of a particular “rarity” — a measure of quality. These figures have been created by a professional artist for the purposes of illustration and are visually similar to the focal game.
discount – around 2.6 million rare loot box opening occasions come from 11 loot boxes opened at once. A user is assumed to have left the game after her last recorded action.

Table 1 presents summary statistics of users playing the game and opening loot boxes. An average consumer plays 38.4 main stages and opens 8 rare loot boxes. She reaches stage 18, receives 78 coins – 72.8 coins through the gameplay and 5.2 through purchase with real money – and plays on 21.2 unique sessions and on 11.4 unique days. However, this distribution is heavily skewed – for instance, the median user opens only 3 rare loot boxes, reaches only stage 4, receives only 18 coins, and plays only one session. The right tail of the distribution is very long, with some players opening more than 6 thousand rare loot boxes, purchasing 50 thousand coins with real money, and playing more than 9 thousand sessions. Figure 12 in Appendix A.1 visualizes this heavy right skew in the users’ play and loot box openings occasions by plotting their joint distribution. Even using a log scale, the distributions are skewed right. The number of plays and loot box openings are highly correlated, showing that users who play a lot also open a lot of loot boxes.

Actions correspond to playing the game or opening lootboxes. A session is defined as a sequence of actions that are no more than 1 hour apart.
In-Game Currency and Loot Box Prices. Our data on currency transactions allows us to distinguish between the acquisition of new currency by completing the main game and by purchasing them. We construct a stock of currency the player has at each in-game action, and record whether this action was made with the currency that the player acquired organically or purchased with hard currency.

The second part of Table 1 presents the resulting summary statistics. Most, 183.2 million out of 196.3 million, or 93.3%, of the in-game currency used is obtained organically. The rest, 13.1 million coins, are obtained through purchases with real money. Out of the purchased coins, players spend 99.8%, or 13 million; these paid coins are spent mostly right after the purchase. Players are less careful in using all of the organically obtained coins – only 155 million, or 87.7%, are spent.

Players can spend their coins on loot boxes or other microtransactions. For instance, a user can pay to continue playing a stage that she is about to lose. However, the acquired coins are mostly spent on loot boxes – 91.1% of total spending and 95.7% of their spending with coins purchased with real money are on loot boxes.

Interestingly, the usage of paid coins is much more concentrated than the organic coins – while 90% of all organic coins are driven by 31.5% of the players, 90% of paid coins are driven only by 1.5% of the players. This difference reflects the notion of the existence of video game “whales”, players who spend disproportionately more money than the rest of the players, and who are crucial for the monetization of freemium video games.

We also observe loot box prices. In most observations (89%), the price of a single loot box is 3 or 5 coins, where 3 is a discounted price for the first time a loot box type is opened. The players face a discounted price of 3 coins on 55.8% of occasions. Similarly, in 88.8% of the observations, the price of an eleven-pack bundle is 40 (discounted) or 50 (regular price). The next two most common price levels of 11-packs of loot boxes, 18 and 25, jointly account for another 6.6% of observations.

Divers, Loot Boxes, and Diver Inventory. We have data on the characteristics of divers, the probabilities of getting different divers from loot boxes, as well as actual loot box realizations. We construct current diver inventory from this data.

There are 2,009 unique divers. Players get divers by making progress in the game, and by opening loot boxes. The two features of the divers that determine their usefulness for the stage game are rarity and color. Rarity is a vertical attribute that determines the overall strength of the diver, varying from 0 to 6 (seven levels). Five colors represent a horizontal attribute, determining the ability of the diver to remove gems of the same color.

We have data on the probability distribution of loot boxes, as well as loot box realizations, from which we construct diver inventory. There are large differences in the divers received from normal and rare loot boxes, stored in the inventory, and used during playing the game (Figure 2). Normal loot boxes are opened with in-game points and are very likely to give lower-quality divers of rarity smaller than three. They are therefore not very relevant for players focused on the functional value of the divers, as most players are likely to have some of the comparable quality in their inventory. In contrast, rare loot boxes almost never provide divers of rarity zero or one, and relatively large probabilities of getting divers of rarity greater than three. Players
Bars correspond to the shares of rarity observed among the corresponding sets of divers.

tend to keep these divers in inventory. Players are more likely to use rare divers in actual play, with divers of rarity four, five, and six played more than the probabilities of receiving them or just having them in inventory. We present a similar picture for diver colors in Figure 13 in Appendix A.1; there are no similar systemic patterns.

4.3 Descriptive Statistics

Game Progress. Throughout our analysis, we focus on the main stage play – the 173 stages that players need to clear sequentially to “complete” the game. Given the sequential nature, early stages see more unique players and plays than later stages (Figure 3). While 2.5 million players play and proceed from stage 1, the number of unique users and plays drops rapidly. The number of unique players is only around 1 million by stage 10. Starting from stage 12, there are occasional spikes in the number of plays per stage. This is because some stages are more difficult than others; players may lose and need to re-play to make progress.

Win Probabilities. In general, higher stages are more difficult. Figure 4 plots win rates by stage, as well as probabilities of opening loot boxes and spending coins. Win rates are calculated by dividing the number of times a stage has been won, by the times the stage was attempted. They are around 95-96% in the first few stages but drop to 81.6% in stage 12, and 65.4% in
Main stage plays and unique players are counted if a player plays a stage that is one higher than the maximum stage won so far; that is, we do not count occasions of players going back and replaying stages they already won before.

stage 16. The win rate roughly drops every 4 stages, which are designed to be difficult as players need to defeat a particularly strong character (a “boss”). Win rates decrease as stages progress, with the final stages of the game having win probabilities only of 47.7-48%.

The lower two lines in Figure 4 present the probabilities of opening at least one rare loot box and of spending at least some coins while at each game stage. Around 12% of players open at least one loot box and 18.8% of players spend at least some coins at an average stage. There is a detectable spike in loot box opening and coins spending after winning stage 3, since that is the end of the game tutorial when players are introduced to rare loot boxes and suggested to open one. Otherwise, spikes in loot box openings and coins spendings occur every four levels, aligned with the harder “boss” stages. They suggest that players tend to open more loot boxes when they are struggling to make progress in the game.

We test the relationship between the complexity of stages and loot box openings by regressing loot box openings and coin spending probabilities on stage win probabilities. Results are presented in Table 2. All variables are in logs, which gives coefficients an interpretation of elasticity estimates based on across-stage correlations. If the win rates of stages are 1 percent lower, the probabilities to open rare loot boxes are 0.77% higher, and probabilities to open a rare loot box for real money are 1% higher. Similarly, on stages with a 1 percent lower win rate players tend to spend 1.7% more coins and 1.4% more coins than they have paid for with real money.

Estimates are similar if we use only the 38 thousand players who reached the final stage. Higher
Win rates are calculated by dividing the number of times a stage has been won, by the times the stage was attempted, using only sequential occasions of main stage plays. Probabilities of opening at least one rare loot box and spending at least some coins (“dream drops”) are calculated by taking an average across players who are at a given stage.

Probabilities of opening loot boxes at stages that are harder suggest the functional value of loot boxes; we investigate this relationship more rigorously in Section 6.

*p<0.1; **p<0.05; ***p<0.01

The variables are constructed similar to Figure 4; all variables are in logs, meaning that coefficients should be interpreted as an effect of 1% change in stage win probability on percent change in the loot box opening and coins spendings probabilities.
**Inventory quality.** As players make process throughout the game, they accumulate more rare divers in their inventory. Figure 5 presents the quality of players’ inventory across stages by summing the rarity level of the top four divers in the inventory; only four top divers are the most relevant for gameplay since players can choose up to four divers to play in a given stage. To make inventories comparable across stages, we only use inventories of players who complete the game (those who win all 173 stages). The average increases from 9 in the early stages up to 21.5 by the end of the game. There is a discrete jump after stage 3 since that is when players open a rare loot box as part of the game’s tutorial.

Figure 5: Average top-4 diver rarity in inventory across stages

![Graph showing the average top-4 diver rarity in inventory across stages](image)

Average inventories are computed by taking the sum of the top four divers’ rarity across players, using only the first observation per player per stage (to make sure player weights are equal across all stages). We use only observations of players who reached and won stage 173.

**Diver value.** How valuable are divers’ rarity for winning in-game stages and making progress? To examine this, we regress a player’s likelihood to win a stage on the summed rarity of the top four divers in their inventory, similar to the variable presented in Figure 5. We allow the effect of the summed rarity of the top four divers to be stage-specific by adding stage-rarity interaction terms, and control for stage and user fixed effects to use only within the stage and within user variation. Figure 6 visualizes the estimated stage-specific coefficients of rarity effects on stage win probabilities. The coefficients are positive and statistically significant (at 5% level; clustering done on the stage level) for 155 out of 173 game stages. On average, one extra rarity point in the sum of rarities across the top four divers increases win probability by 2 percentage points.

12 Appendix A.2 presents the estimates from alternative specifications of regressions, that examine the effect of the rarity of divers in players’ inventories on players’ win probabilities. The effect of a rarity on win probabilities is consistently strong across different parametric assumptions.
Out of 18 stages with insignificant estimates of the effects of diver rarities on win probabilities, 10 are in the first 13 stages, presumably because these stages are relatively simple. There is a very slight increase in the magnitude of the effect of diver rarities on win probabilities as the players progress to more advanced game stages, with the fitted effect of inventory rarity on win probabilities increasing from 1.5 percentage points in stage 1 to 2.5 percentage points in stage 173. Overall, these results confirm that diver rarity has strong functional value in the game, and that this functional value of acquiring extra divers is relatively constant throughout the stages.

Figure 6: Effect of extra rarity point on stage win probability

Each point represents a stage-specific estimate of the effect of the rarity of top four divers in players’ inventories on stage win probabilities of these players. To compute these effects, we regress a player’s likelihood to win a stage on the summed rarity of the top four divers in their inventory, similar to the variable constructed in Figure 5. We allow the effect of the summed rarity of the top four divers to be stage-specific by adding stage-rarity interaction terms, and control for stage and user fixed effects to use only within the stage and within user variation. Standard errors are clustered at the stage level.

Returns to loot boxes. Results so far provide strong suggestive evidence for the existence of the functional value behind loot boxes for players. We have shown that players tend to open more loot boxes at stages they lose, and extra diver rarity they can collect increases their win
probabilities. Yet, the combination of evidence presented in Figures 4 and 5 – that the rate of opening loot boxes is relatively flat across stages but that the quality of players’ inventory is much higher in later stages – is hard to rationalize with the functional value of loot box openings. The “return” from loot boxes – expected increases in top divers’ rarity – are likely much higher in the early stages than in the latter stages of the game. In the early stages, the quality of the inventory of players is low, and players are yet to accumulate strong inventories. This means that if loot box openings were driven by the functional values of divers, players should have been more likely to open them early on in the game to build the inventory faster. Yet, the behavior of players does not reflect this: their propensity to open loot boxes is flat across stages.

To make this argument more salient, in Figure 7 we visualize the implied “return” from loot boxes in terms of the top divers’ rarity. In Panels (a) and (b), we present the probabilities to open a rare loot box per stage of the game – overall (a) and using real money (b) - which closely follow related probabilities from Figure 4 above and 15 in Appendix A.1, and are nearly flat across game stages. In the average stage, the user opens a loot box 16.2% of the time and opens it using real money 1.1% of the time. In Panel (c), we visualize the “return” from loot boxes, the expected change in rarity of the top four divers if a player opens one rare loot box. The expected increase in the rarity of top divers in players’ inventories is around 0.25-1 in the early stages of the game – meaning that for every loot box opened, a player can expect the rarity of one of the top four divers to go up by 0.25-1 points. It goes down dramatically in the later stages of the game, all the way to around 0.006-0.01 in the last 50 stages. Such a dramatic decrease in the return from loot boxes is not due to their lower probability to provide high rarity divers, but rather because players have already amassed good inventories.

Panel (d) of Figure 7 presents the number of loot boxes a player needs to open to expect to increase their win probability by 1 percentage point – a variable directly capturing the inverse of the immediate functional value a player extracts from opening a loot box. We compute this by combining the expected increase in top diver rarity in players’ inventory across stages (Panel c) with the effect of one extra rarity point on stage win probability (Figure 6). Panel (d) reveals that the functional value of loot boxes dramatically falls across stages; in early stages, 1-2 loot boxes are enough to increase players’ win rate by 1 percentage point, while in later stages a player needs to open 50-60 loot boxes to increase win rate by 1 percentage point. Jointly, Panels (a), (b), and (d) of Figure 7 strongly suggest that loot boxes openings do not reflect on their functional value – even if we focus only on the immediate returns from loot boxes.

Impulsive openings of loot boxes. Given the lack of correlation between the probability of opening loot boxes and their implied returns, we further investigate the potential drivers of loot box consumption. Data suggests that impulsive consumption due to self-control problems likely plays a prominent role. First, players are much more likely to open a loot box right after

Accounting for long-term effects of having high rarity divers in the inventory makes this argument even stronger since the returns from opening loot boxes early on in the game are even higher – early on in the game players may expect to be using divers for more stages.

Lockwood et al. [2021] identify self-control problems as one of the key behavioral biases underlying playing state lotteries. The other two major factors that explained biased consumption of lotteries are financial illiteracy and statistical mistakes, both of which are less important in the context of loot boxes: big financial decisions are not on the line in this context, and loot box probabilities are directly presented to players.
Panels (a) and (b) present probabilities to open a rare loot box per stage of the game, overall and using real money. Panel (c) presents the average change in the rarity of the top four divers in a player’s inventory after opening a rare loot box at different stages of the game. Panel (d) presents the number of loot boxes a player needs to open to expect to increase their win probability by 1 percentage point. The expected number of loot boxes is computed by dividing 0.01 by the average change in the rarity of the top four divers in a player’s inventory after opening a rare loot box and multiplying by the fitted values from Figure 6, the effect of one rarity point on win probabilities.
another loot box; on average, the probability to open a loot box after playing the stage is 7.7%, whereas it is 67.7% after opening another loot box. Such back-to-back opening of loot boxes is indicative of impulsive consumption, since the consumer sees a loot box on the screen again after not getting what they want and is compelled to try again.

Second, the vast majority of these back-to-back loot box openings happen with almost no time gap in between. The median time between two back-to-back loot box openings is 19 seconds, including a 15-second animation video of a loot box opening. This implies that a median consumer decides to open another loot box in just 4 seconds. In contrast, the median time between opening a loot box and playing the game stage is 122 seconds, even though switching to play the game only takes 2-3 taps on the screen. Such a short time span between two subsequent loot box openings suggests limited consideration of which action to take next, consistent with impulsive behavior.

**Currency constraints.** Finally, we examine whether currency constraints play a role in players’ decisions to open loot boxes. When players want to open a loot box but do not have enough in-game currency to do it, they face a trade-off between playing more and accumulating enough in-game currency, or making a purchase of coins with real money. To understand whether such constraints are binding, we plot the probability of opening a loot box by the accumulated amount of the in-game currency in Figure 8a. There are four clear spikes at 3, 5, 40, and 50 coins, corresponding to the prices of 1 and 11 loot boxes (3 is a discounted price sometimes offered instead of 5, and 40 instead of 50). This result shows evidence that constraints are binding. The players may be forward-looking in waiting for more coins to open more loot boxes for a discounted price. To confirm that this effect is not driven by other factors, Figure 8b plots the probability to open a loot box using paid coins, which can be purchased at any point. Results are strikingly different; there are no spikes at the stocks of 3 and 5 coins. There are only small spikes at the stock of 40 and 50 coins, potentially corresponding to players using the coins they have purchased earlier.

## 5 Model

We now turn to building a more formal model of gaming with loot boxes that is tailored to the data that we use.

A player $i$ makes progress sequentially through 173 stages. After the player completes all stages, she can continue replaying the stages. On choice occasion $t$, player $i$ decides one of four actions $a_{it}$ to take: play the game ($a_{it} = 1$), open a single loot box $L_{rt}$ ($a_{it} = 2$), open an eleven pack of loot boxes ($a_{it} = 3$), or leave the game forever ($a_{it} = 0$). The player makes these decisions given the inventory of the divers that she holds, $D_{it}$; the accumulated stock of the in-game currency, $c_{it}$; the current stage she is playing $s_{it}$; an indicator whether the player has lost round $q_{it}$ before; a variable $d_{it}$ that captures state dependence in loot box openings in a primitive fashion, as we define below; and prices of opening one and eleven loot boxes, $p_{it}^1$ and $p_{it}^{11}$.

---

15 Visual stimuli are common triggers for impulsive choices; e.g. see Rook [1987].
Figure 8: Probability of Opening Rare Loot Box Given the Current Stock of Coins.

(a) Opened Using Any Coins

(b) Opened Using Paid Coins

The currency stock is computed using the observations of users’ currency transactions.
Playing the stage game \((a_{it} = 1)\). The non-random contemporaneous utility of choosing \(a_{it} = 1\) is

\[
u(a_{it} = 1) = \alpha_{G,s_{it}} - \beta q_{it}
\]

where \(\alpha_{G,s_{it}} = \alpha_{G,s}\) is the stage-specific utility of playing the stage game, and \(q_{it}\) is an indicator variable that takes the value of one if the player has lost the current stage \(s\) before. This captures the disutility of the player of losing and having to reply the same stage. In the empirical context, players make progress through a sequential series of stages. The \(-\beta\) captures the disutility of having lost the current stage and having to replay it – anticipating this, players may seek better characters to make progress in the game. The parameter is assumed to be common across players and stages.

Opening a single loot box \((a_{it} = 2)\). Instead of playing the stage, a consumer can open loot boxes. Consider the case of \(a_{it} = 2\), in which the player opens one loot box. We assume that the loot box a player can open is determined by the current stage, \(L_s = L_{s_{it}}\). With probability \(Pr_s\) she gets a diver \(d\) from a loot box \(L_s, d \in D_{L_s}\), updating her inventory of divers to \(D_{i,t+1} = \{D_{it}, d\}\). \(^{16}\)

Opening a loot box comes at a cost of \(p_{1it}\) coins, subtracted from the stock of in-game currency, \(c_{i,t+1} = c_{it} - p_{1it} \) \(^{17}\). Following the expenditure patterns of in-game currency, we assume that depletion from the stock itself is not utility decreasing. The stock is likely to consist mainly of coins obtained for free, which consumers do not fully use. On the other hand, if \(p_{1it} > c_i\), the consumer spends hard currency to purchase \(p_{1it} - c_{it}\) drops.

A consumer obtains (constant) direct thrill utility from opening a loot box, \(\alpha_{L,1}\). On top of this, if a consumer opens a loot box immediately after another loot box, she gets an extra thrill value \(\eta\), a proxy for the impulsive openings of loot boxes. We capture this behavior with an indicator variable \(d\) that captures if the play’s previous action was also to open a loot box,

\[
d_{it} = 1 (a_{i,t-1} \in \{2, 3\}).
\]

Combining these terms, the non-random component of utility from action \(a_{it} = 2\) is

\[
u(a_{it} = 2) = \alpha_{L,1} - \gamma 1 (p_{1it} > c_{it}) \times (p_{1it} - c_{it}) + \eta d_{it} \tag{5}
\]

where \(\gamma\) is the marginal (dis)utility of purchasing coins.

Opening an eleven-pack of loot boxes \((a_{it} = 3)\). As we described previously, distinguishing between purchases of one and eleven-packs of loot boxes is important given the non-linear pricing. We allow for a separate option for consumers to open eleven loot boxes, introducing action-specific coefficients on direct utility \((\alpha_{L,11})\), as well as a purchase \((\gamma)\) and state-dependence \((\eta)\) coefficients. The non-random component of utility from choosing \(a_{it} = 3\)

\(^{16}\)Inventory has a capacity constraint. If the constraint is met, we assume the player keeps the best divers.

\(^{17}\)The price \(p_{1it}\) can vary by player and play occasion since price discounts can depend on the timing of play, as well on the previous actions of the player, as we discuss in Section 4.2.
Choosing to leave the game ($a_{it} = 0$). A player can choose to leave the game forever, $a_{it\tau} = 0$. The terminal utility is normalized to zero,

$$u(a_{it} = 0) = 0.$$  

Utility maximization. Given these choice-specific utilities, the player $i$ decides on an action $a_{ij}$ that maximizes the present-discounted value of the future stream of utilities,

$$\max_{a_{it}} \mathbb{E}\sum_{t=1}^{\infty} \beta^{t-1} [u(a_{it}; O_{it}; \theta) + \varepsilon_{iat}]$$  

where $\theta$ are the model parameters to be estimated, $O_{it} = \{R_{it}, c_{it}, s_{it}, q_{it}, d_{it}, p_{it}^{1}, p_{it}^{11}\}$ are state variables, and $\varepsilon_{iat}$ are player, choice, time specific idiosyncratic shocks.

Using Bellman’s equation, we define the value function as

$$V(O_{it}, \varepsilon_{iat}) = \max_{a_{it} \in \{0, 1, 2, 3\}} u(a_{it}) + \varepsilon_{iat} + \beta E_{O', \varepsilon'|O_{it}, a_{it}} V(O', \varepsilon')$$

Assuming that the idiosyncratic shock $\varepsilon_{iat}$ is distributed Type-1 extreme value, we can express the conditional choice probabilities of choosing action $a_{it}$ as

$$CCP(a_{it}|O_{it}) = \frac{\exp \left( u(a_{it}) + \beta E_{O', \varepsilon'|O_{it}, a_{it}} V(O', \varepsilon') \right)}{\sum_{\tilde{a}_{it} \in \{0, 1, 2, 3\}} \exp \left( u(\tilde{a}_{it}) + \beta E_{O', \varepsilon'|O_{it}, \tilde{a}_{it}} V(O', \varepsilon') \right)}$$

State Transitions. Here we summarize the transitions of the state variables $O_{it}$. We discuss the empirical estimates of transition probabilities in Section 7 and Appendix A.3.

There are two sources of updates to diver inventory, $D_{ij}$ – the player receives divers when making progress in the game and when opening loot boxes.

The currency stock, $c_{ij}$, is also updated either via organic in-game progress as she makes progress in the stage game, or purchases of the currency with real money. Currency decreases by as much as $p_{it}^{1}$ or $p_{it}^{11}$ when the player chooses to open a loot box.

The current stage of the game, $s_{it}$, is updated when a player wins the stage. The win probability is affected by which stage the player is on (stages differ in complexity), what is the rarity of divers in the player’s inventory, and whether the player has lost this stage before (they play it the second time), $Pr(win|s_{it}, q_{it}, D_{it})$. To make the estimation of the effect of the player’s inventory on win probability tractable, we approximate the player’s inventory as a function of the rarity of divers she has, as rarity is the primary vertical dimension by which divers are differentiated functionally. For this, we track the top four rarity divers, as players can use at most four divers from inventory for any given stage of gameplay. We then create a single index, $R_{it} = \sum_{l=1}^{4} \text{rarity}_{itl}$, a summed rarity of the top four divers in the inventory\footnote{Since divers of rarities 0-2 do not vary much in their characteristics, we pool them together and assign them...}.

\[\text{Electronic copy available at: https://ssrn.com/abstract=4355019}\]
The probability to win is

$$\Pr(\text{win}|s_{it}, q_{it}, D_{it}) = \zeta_{1,s,q} + \zeta_{2,s,q} \times R_{it} + \zeta_{3,R_{it}}$$ (11)

where $R_{it}$ summarizes the rarity of divers in player $i$’s inventory at time $t$. Coefficients $\zeta_{1,s,q}$, $\zeta_{2,s,q}$ and $\zeta_{3,R_{it}}$ allow for stage-and-loss-specific effects of inventory rarity on the win probability.\(^{19}\)

When the player loses a stage, $s_{it+1}$ is not updated ($s_{it+1} = s_{it}$) and $q_{it+1}$ is updated to one ($q_{it+1} = 1$). If she wins a stage, $s_{it+1}$ is updated to $s_{it} + 1$ and $q_{it+1}$ is set to zero.

The state-dependence variable $d_{it}$ is updated using the formula in Equation 4.

The transition of the loot box prices mainly depends on the previous actions of the player. The player faces a discounted price the first time she opens a single or eleven-bundle of loot boxes. We allow price states to transition across states $\{-3,-5\}$ for one loot box and $\{-18,-25,-40,-50\}$ for eleven-packs) given the empirical distribution of these transition probabilities conditional on stages and past actions of players to account for other occasional discounts.

6 Model-free Evidence

Before estimating the full model, we examine players’ decisions to play and open loot boxes. While we need a full model to account for players’ forward-looking behavior and expectations about state transitions, short-term reactions of players to changes in stages provide us with an informative prior on the direction and magnitudes of players’ preference estimates – including the functional and direct value they derive from loot boxes. In this model-free exercise, we leverage two sets of random state realizations throughout the game – whether the player ended up winning or losing the stage game (keeping their skill, inventory, and progress so far constant), and the rarity of a diver she received after opening a loot box.

6.1 Effect of Winning the Stage

In equation 3 above, we have assumed that players have two sources of utility from gameplay – the value of playing ($\alpha$) and of winning stages ($\beta$). The second component, the value of winning, is parameterized with an indicator of whether the player has lost this stage before, $q_{it}$. Whether the player wins or loses the stage depends in part on their skill, accumulated inventory, and game stage, all of which are states we observe and can control for. However, it also depends on realizations of stage complexity, driven by how close different colors of gemstones are (randomly) allocated throughout the stage. We leverage this randomness in players’ stage performances to examine the effect of winning or losing on immediate play and loot box decisions.

We measure the effect of stage loss on the probability to open a loot box (instead of playing again) by estimating

$$I(a_{it} \in \{2, 3\}|a_{i,t-1} = 1) = \kappa_{i} + \kappa_s + c \times I(\text{win}_{i,t-1}) + \xi_{it},$$ (12)

where $\kappa$ parameters correspond to user and stage fixed effects\(^{20}\) and $I(\text{win}_{i,t-1})$ is an indicator for

\(^{20}\) Result are robust after adding additional (e.g. day, stage by inventory rarity) fixed effects.
of whether the player has just won while playing the game in the previous choice occasion. All observations used are conditional on playing the game in period \( t - 1 \). We use only playing the main stage and opening rare loot boxes as two types of actions available. We cluster the standard errors two-way, on the user and stage level.

All observations are conditional on the user playing a main stage in period \( t - 1 \). All specifications include stage and user fixed effects. All standard errors are clustered two-way, on the user and stage level.

Table 3 presents the results of estimating Equation 12 on varying subsets of data. In Column (1), we present the effect of winning the stage on the probability to open a loot box based on all relevant observations in our data. If a player just won the game, she is 3.83 percentage points less like to open a loot box – a 50% decrease in loot box play probability compared to the baseline average of loot box openings (after playing the stage) of 7.7 percentage points. The probability to play another stage respectively increases by 3.83 percentage points.

In Columns (2) and (3), we split the sample by game stages, estimating the effect separately for players in the first and second half of the game (below and above stage 87, respectively). Point estimates of the effect of a stage win on the rate of opening loot boxes are slightly stronger early on in the game – a win decreases the loot box opening probability by 4.4 and 2.7 percentage points before and after stage 87, respectively – but given the standard errors this difference is only marginally significant.

In Columns (4) and (5), we now split the sample into two types of players. In particular, we identify players who are top spenders in the game – 1.5% of players who generate 90% of revenues of the game by purchasing coins for real money. Following our discussion in Section 4.2, we label these high-spending players “whales.” There is a total of 37,294 players in this group responsible for 10,132,617/95,617,205 \( \approx 10.6\% \) of all in-game actions.

We find that the effect of a stage win on the rate of opening loot boxes is slightly stronger for non-whales than for whales – a win decreases the loot box opening probability by 3.9 and
2.9 percentage points for non-whales and whales, respectively. However, the estimates are not significantly different. Overall, the estimates across all groups in Table 3 confirm that losing a stage decreases the value of play for users, consistent with the preference for winning in the game. The switching of consumers to opening loot boxes also suggests the presence of functional value, since opening loot boxes helps players win. We investigate this further next.

6.2 Effect of the Loot Box Outcomes

Above, we have shown that players dislike losing in the game and are more likely to open a rare loot box after a loss – the behavior consistent with the functional value of the items they can get from loot boxes. Yet, such avoidance of gameplay after a loss can indicate a distaste for repeating the same game stage (to make progress in the game) and not a preference for building and using a better inventory. We now examine the effect of players’ building the rarity of their inventory on the gameplay and loot box opening decisions.

If loot boxes have functional value for players, loot box random realizations that provide more rare divers should increase users’ expected play utility by improving their inventory. To examine the effect of players’ inventory rarity and loot box outcomes, we estimate

$$I(a_{it} \in \{2, 3\}|a_{i,t-1} \in \{2, 3\}) = \kappa_i + \kappa'_{s,R_{it-1}} + bR_{it} + \xi_{it},$$

(13)

where \(\kappa\) parameters correspond to user and stage by inventory rarity (top four divers) in period \(t - 1\) fixed effects and \(R_{it}\) is the inventory rarity in period \(t\). All observations used are conditional on opening a loot box in period \(t - 1\). As above, we use only playing the main stage and opening rare loot boxes as two types of actions available. We cluster the standard errors two-ways at the user and stage level.

Since players can have different rates of loot box openings – and players who opened more loot boxes in the past are both more likely to have accumulated better inventory and to open more loot boxes in the future – we cannot regress \(I(a_{it} \in \{2, 3\}|a_{i,t-1} \in \{2, 3\})\) on \(R_{it}\) directly. Instead, we instrument for \(R_{it}\) with rarity \(L_{it-1}\), the realization of diver rarity from the loot box that the player just opened in period \(t - 1\). By construction, this rarity realization is random and has an impact on a player’s inventory before it is built up to a perfect level, making it a valid instrument.

The first part of Table 4 presents the estimates of \(b\) from the instrumental variable regression as well as first stage results, using all players in our data. Column (1) presents the estimates for the entire sample. On average, one extra rarity point of the diver received from a loot box by players, rarity \(L_{it-1}\), increases the rarity of the top four divers in a player’s inventory on average by 0.123 points. This increase, in turn, decreases the probability that a player opens another loot box by 0.151 * 0.123 * 100 = 1.86 percentage points. Put differently, a full point increase in \(R_{it}\) on average corresponds to a 100 * 0.151/67.7 \approx 22.3% decrease in the baseline probability to keep opening loot boxes.

An average effect based on the entire sample masks important differences in random realizations of loot boxes. As we have discussed above, drawing more rare divers should be more

21 We abuse notation by using the same notation for the nuisance parameters as in regression 12.
22 If a player opens a pack of loot boxes at once, we count the highest rarity among divers drawn as rarity \(L_{it-1}\).

</table>

*All observations are conditional on the user opening a rare loot box in period $t-1$. All specifications include stage-by-rarity inventory in period $t-1$ and user fixed effects. All standard errors are clustered two-way, on the user and stage level.

Important for players with a less developed inventory. To examine the difference in the effects of rarity$_{L_{it-1}}$ on gameplay, Columns (2) and (3) of the first part of Table 4 break down the
sample to players with inventory in \( t - 1 \) below and above 16 points. As expected, the effect of rarity \( L_{it-1} \) realization on diver inventory \( R_{it} \) is much more pronounced for players with less developed inventories. A one-point increase in the rarity of a received diver improves the top four diver rarity in the inventory by the expected 0.445 points if the inventory rarity was below 16, but only by 0.026 points if the inventory rarity was above 16. The implied effects of one extra rarity \( L_{it-1} \) point on the probabilities to open another loot box are 0.084 * 0.445 * 100 = 3.74 and 0.646 * 0.026 * 100 = 1.68 percentage points decrease, respectively. The latter effect is smaller particularly since one rarity \( L_{it-1} \) point is less useful for players with stronger inventories. Overall, both effects confirm that players are more likely to switch to playing the game if the quality of their inventory improves.

The second and third parts of Table 4 further splits the sample by players who are non-whales and whales. For non-whales (part II) we find that results are similar to the full sample – all columns show that getting a better diver from a loot box increases the players’ probability to switch from opening loot boxes to playing the game, and the effects are stronger for players with less developed inventories. The magnitudes of the estimates are similar to the magnitudes in part I based on the full sample of players.

For whales (part III), the results are drastically different. While the first stage effects are the same as before – the effect of one extra rarity \( L_{it-1} \) point on diver inventory \( R_{it} \) is 0.424 for the subset with \( R_{it-1} < 16 \) (Column 2) and 0.015 for the subset of observations with \( R_{it-1} \geq 16 \) (Column 3) – the implied effects of incremental \( R_{it} \) on gameplay or loot box opening decisions are much smaller. First, for whales with weaker inventory, \( R_{it-1} < 16 \), improvement of the inventory \( (R_{it}) \) by one extra rarity point decreases their probability to open another loot box only by 3.1 percentage points – in contrast to 8.8 percentage points for non-whales. This implies that one extra rarity point in rarity \( L_{it-1} \) realization decreases the probability that a player opens another loot box by 0.031 * 0.424 * 100 = 1.31 percentage points (3.9 for non-whales). For whales with stronger inventory, \( R_{it-1} \geq 16 \), there is no detectable effect of the improvement of the inventory \( (R_{it}) \) on loot box opening decisions. The effect of one extra rarity point in rarity \( L_{it-1} \) on a player’s probability to loot again is 0.0212 * 0.0152 * 100 = 0.03 percentage points, an effect that is estimated very precisely (standard error of 0.133, projecting \( I(a_{it} \in \{2,3\}|a_{i,t-1} \in \{2,3\}) \) directly on rarity \( L_{it-1} \)).

**Taking stock.** Overall, the results above provide three important takeaways for our analysis. First, we have shown that loot boxes have a functional value for the majority of the players – a better diver rarity draw increases the probability to jump into the game instead of opening another loot box.

Second, results indicate that the preferences of whales in terms of the functional value of loot boxes are drastically different from non-whales – whales react much less to the realization of the rarity of divers they receive from loot boxes, indicating that other mechanisms are driving their loot box consumption.

Third, while players react to the acquisition of more rare divers, such variation can explain only a small fraction of loot box openings. In contrast, sequences of actions explain much larger variation in loot box openings. To see this, compare averages probabilities of opening a loot box immediately after playing the stage, \( I(a_{it} \in \{2,3\}|a_{i,t-1} = 1) \) (Table 3), and after opening
another loot box, $I(a_{it} \in \{2,3\}|a_{i,t-1} \in \{2,3\})$ (Table 4). After an average user plays the game stage, her probability to open a loot box is 7.7%, whereas this probability is 67.7% after she opens a loot box in period $t - 1$. This high likelihood of back-to-back loot box openings suggests strong state dependence in loot box consumption, a behavior that we use as a proxy for impulsive consumption due to a very short time span between two loot box openings (see Section 4.3). To quantify the relative importance of the functional and direct values of loot boxes – including an overall thrill and state dependence value – we proceed to estimating the structural model.

7 Estimation

To estimate users’ tastes, we use a two-step procedure as in Hotz and Miller [1993]. Below we describe how we operationalize the state space and estimate empirical conditional choice probabilities (CCPs). We then describe how the terminal action of users – leaving the game – simplifies the estimation procedure, following Arcidiacono and Miller [2011].

States. In our model, the state variables are $O_{it} = \{R_{it}, c_{it}, s_{it}, q_{it}, d_{it}, p_{1it}, p_{11it}\}$. There are 17 states of $R_{it}$, the sum of the rarity for the top four divers. We allow for currency stock to lie between integers of 0 and 51, as this captures the vast majority of observations and the full range of observed loot box prices. The user’s current stage $s_{it}$ ranges from 0 to 173. The indicator for whether the player has lost the stage, $q_{it}$, and the state-dependence state, $d_{it}$, both vary between zero and one — or 2 levels. Finally, the price of a single loot box opening takes one of two states, $\{3,5\}$, while the price of a bundle of eleven loot boxes takes four price levels, $\{18,25,40,50\}$. Thus, there is a total of 4.9 million possible states.

We estimate the state transition probability matrices from the data, using equation 11 for the win probability estimates and frequency estimators for the rest of the state variables. Appendix A.3 provides more details on the estimation procedure and estimates.

Terminal Action Conditional Choice Probabilities (CCPs) Estimation. CCPs are the probability that an agent optimally chooses an action $a$ given her current state $O$.

We estimate the model parameters using empirical estimates of the CCP for the terminal action $a_{it} = 0$. To see why we only need the CCP of leaving the game for estimating the utility parameters, note that we can express the integrated value function, $\int_{\epsilon_{it}} V(O_{it}, \epsilon_{iat}) dF(\epsilon_{iat})$, as a function (denoted by $\psi(\cdot)$) of the CCPs and the choice-specific value function $v_a(O_{it}) = u(a|O_{it}) + E_{O', \epsilon' |O_{it}, a_{it}} V(O', \epsilon')$,

$$\int_{\epsilon_{it}} V(O_{it}, \epsilon_{iat}) dF(\epsilon_{iat}) = \psi_a [CCP(a|O_{it})] + v_a(O_{it}).$$ (14)

as shown by Arcidiacono and Miller [2011]. Using this expression for the terminal action, $a = 0$, and the properties of the Type-1 extreme value distribution of $\epsilon_{it}$, we get that

$$\int_{\epsilon_{it}} V(O_{it}, \epsilon_{it}) dF(\epsilon_{iat}) = -\log (CCP(a_{it} = 0|O_{it}))) + (\text{Euler constant}),$$ (15)

where $CCP(a_{it} = 0|O_{it})$ is the conditional choice probability of the terminal action.
We can directly estimate the empirical analog of the CCP for the terminal action \( a_{it} = 0 \) from the data. We fit

\[
1\{a_{it} = 0\} R_{it} + c_{it} s_{it} + q_{it} d_{it} = a_{sq}^1 + a_{sd}^2 + a_{sq}^3 R_{it} + a_{sq}^4 c_{it} + a_{sq}^5 s_{it} + a_{sq}^6 d_{it} + \xi_{it},
\]

where \( a \) are the coefficients of interest. To keep the relationship between the states and players’ actions flexible, we allow for stage-by-lose indicator and stage-by-state-dependence parameter fixed effects (\( a_{sq}^1 \) and \( a_{sd}^2 \)), the stage-by-loss-specific slopes on the rarity of the inventory (\( a_{sq}^3 \)), and the stage-specific third order polynomials of the currency stock.\(^{23}\)

Utility Parameters’ Estimation. Given the empirical estimates of the terminal CCPs, we estimate the parameters of the players’ utilities using a simple weighted least squares regression. This requires us to obtain estimates for \( \beta E_{O_t,c'|O_t,a_{it}} V(O',c') \) for each state \( O_{it} \) and action \( a_{it} \) combination.

Using Equation \(15\) we obtain estimates of \( \int c_{it} V(O_{it},c_{it}) dF(\epsilon_{it}) \) from empirical terminal CCPs. Then, using transition probabilities of the state variables estimated in the first step, we compute the expected value function, \( \beta E_{O_t,c'|O_t,a_{it}} V(O',c') \), by integrating over the expected transitions of the states and the chosen action. We set \( \beta = 0.99 \).\(^{24}\)

These estimates of \( \beta E_{O_t,c'|O_t,a_{it}} V(O',c') \) allow us to express the current period utilities of consumers’ actions using the inversion in Berry [1994],

\[
\log(sh_{it}^a) - \log(sh_{it}^0) - \beta E_{O_t,c'|O_t,a_{it}} V(O',c') = u(a_{it}) + \xi_{it},
\]

where \( sh_{it}^a \) are the empirical probabilities of choosing this action in this state observed in the data, and \( \xi_{it} \) is the idiosyncratic shock to the probabilities of choosing this stage. With the estimates of \( \beta E_{O_t,c'|O_t,a_{it}} V(O',c') \) from the first stage, we can compute the left-hand side of Equation \(17\) directly from the data, and the right-hand side of this equation is linear in the parameters defined in Equations \(16\)\(^{24}\). Observations are weighted by the number of realized observations of each state. Confidence intervals are computed using Bayesian bootstrap [Rubin 1981], with clustering (draws of observation weights) done at the stage level.

From Equations \(16\)\(^{24}\) there are 179 utility parameters of interest – baseline utility from playing stages (174 parameters), tastes to open 1 or 11 loot boxes (2), the state dependence parameter (1), the player’s preference not to be in the losing state (1), and the player’s disutility from spending on loot boxes (1).

8 Results

We estimate the structural model for non-whales and whales separately. We visualize the estimates of consumer tastes for the stage play in lieu of a table with extra 174 parameters.

\(^{23}\)Our parameter estimates are robust to alternative approximations of CCP(\( a_{it} = 0 | O_{it} \)), such as additionally including rarity fixed effects, removing stage-by-loss interactions, and allowing for different slopes for when a player does and does not have enough currency to open one loot box for a regular price of 5 coins. The probability of choosing to leave the game does not depend on loot box prices; this is because we do not observe the price of a loot box if the player has chosen the terminal action. We have experimented with the parametric assumptions in the CCP\(_0\) estimation; the functional form is flexible enough to account for non-linearities in the CCPs.

\(^{24}\)Preference estimates are robust to using alternative values of 0.9 and 0.9999.
The utility from playing (Figure 9) increases over the first several stages – especially for non-whales – and fluctuates subsequently. This is aligned with the design of the game: the first 10-15 stages are relatively simple to complete, whereas the latter stages are more difficult. For non-whales, stage utility is increasing in the first part of the game, indicating that they put more weight on making progress in the game and reaching later stages. Further, both non-whales and whales derive more utility from playing harder stages. The cyclical game design, i.e. a boss stage every 4 stages (Section 4.3), is also consistent with the fluctuations in stage utilities.

Standard errors are computed using Bayesian bootstrap, with clustering (draws of observation weights) done at the stage level.

Table 5 presents the rest of the estimated utility parameters. Both non-whales and whales prefer playing the game to opening loot boxes – the average stage fixed effect is around 1.5-2 utils for both types of players, while the average preference for opening one or loot boxes is -1.72 for non-whales and 0.11 for whales. However, both non-whales and whales exhibit state dependence in loot box consumption, with the magnitude of the state dependence more...
pronounced for whales than non-whales (2.02 versus 1.13 extra utils if another loot box has just been opened). Players do not get much of a direct value from an eleven-pack of loot boxes over one loot box. Demand for loot boxes is negatively sloping for both non-whales and whales, with a slightly steeper slope for non-whales (-0.2 versus -0.15). Finally, both non-whales and whales dislike losing in the game and getting stuck on one level. The magnitude of the effect is stronger for whales.

### 8.1 Heterogeneity of Players’ Tastes

In our main specification, we allow for heterogeneity along players’ monetary importance for the gaming company – whales, the 1.5% of players who are responsible for 90% of revenues, and non-whales, the rest of the players. Splitting the sample by players’ in-game spending is important for understanding a key trade-off: should the company target the design of the game and loot box toward a small minority of paying customers? Or should it target the vast majority of non-paying customers who are still enjoying the game and promote it, either directly through word-of-mouth or indirectly through the apps’ rankings in the app store?

However, how much players spend might be not the only critical dimension of heterogeneity for characterizing tastes. This is particularly important since we estimate a reduced-form state dependence parameter, and interpret it as capturing the degree of players’ impulsive consumption of loot boxes. Past literature has shown that not accounting for heterogeneity can inflate state dependence estimates [e.g. Dubé et al., 2010; Simonov et al., 2020].

We extend our analysis in two ways to test whether parameter estimates, particularly the degree of state dependence in players’ choices of loot boxes, vary when we allow for more heterogeneity. First, we split the sample of players along a different dimension – how many events the players have participated in throughout the game. Game events do not count as stage-play in our estimation so clustering does not rely on our main data sample, but the degree to which players participate in events should capture their engagement with the game. We group the top 10% of players by participation in events as high-engagement players, corresponding to those who have participated at least in 50 event games. As expected, high-engagement events players are also heavier players of the main stages of the game and open more loot boxes. As a group, they are responsible for 55.6% of all main stage plays and 58% of rare loot box openings. Table 6 presents parameter estimates for low- and high-engagement players of event games. Parameter estimates are consistent across the two groups – they share the same level of state dependence preferences, preferences for eleven-pack loot box, payment, and past loss of the played stage. The only significant difference in the preferences of low- and high-engagement players of event games is their preference for loot boxes over the gameplay – high-engagement stage players also have a higher preference for opening loot boxes – which is expected since their players are more invested in the game.

In our second extension of the heterogeneity analysis, we separate out whales and non-whales into additional clusters based on the player-level propensities to play main-stage games over opening loot boxes. For this, we cluster players based on their average preference for playing the main stage – overall and conditional on different levels of currency, rarity, loss, and state dependence states – and allow for two separate clusters (high and low preference for gameplay).

Players are grouped by the number of special events they participate in. Standard errors are computed using Bayesian bootstrap, with clustering (draws of observation weights) done at the stage level.

The resulting clusters are approximately equal in size – 52% of non-whales and 45% of whales are allocated in the high-preference for gameplay cluster.

Table 7 presents the estimates for all four groups of players – whales and non-whales with high and low preferences for gameplay. As expected, in both groups players with a high preference for gameplay have lower estimates of their preferences for loot boxes. The state dependence tastes of players are consistent across high- and low-preference for gameplay clusters for whales – for both groups, η estimates are around 2-2.1 – whereas for non-whales low-preference for gameplay cluster (cluster 1) exhibits negative but only marginally significant state dependence in loot boxes opening (η estimate is -0.63 with a standard error of 0.31). Non-whales are more price elastic compared to whales in both high- and low-preference for gameplay groups. Finally, the high-preference for gameplay group (cluster 2) does not care as much about losing the game, but overall losses are still more costly for whales compared to non-whales.

Standard errors are computed using Bayesian bootstrap, with clustering (draws of observation weights) done at the stage level.

Overall, we conclude that state dependence of users’ choices of loot boxes is prominent even if we allow for more heterogeneity in consumer preferences, in the dimension of players’ preferences for play over loot boxes. We confirm that our key takeaways are robust to allowing for

---

25To measure players’ average preference for playing the main stage, we compute residuals in a linear probability model of playing the main stages of the game over opening loot boxes using the same parameterization of the model as in equation 16 (which allows us to control for the state in which a player makes the choice). We then use k-means clustering based on averages of the residuals for the player, with residuals unweighted and interacted with the current levels of currency, rarity, loss, and state dependence.

heterogeneity within the groups of whales and non-whales when we decompose the mechanisms behind the loot box value for players.

9 Loot Box Value Decomposition and Counterfactuals

We use our estimates of players' tastes to examine their implications for product design and policy. To start, we decompose the value that players associate with loot box opening. We, therefore, provide a direct answer to the question of why consumers purchase loot boxes: Do loot boxes play a complementary role to the consumption of the main video game content, or do consumers obtain utility from loot boxes in and of itself? We then illustrate the role that loot boxes play in the overall game design through a series of counterfactual simulations where we manipulate the design of the game and loot boxes, and subject players to policy interventions.

9.1 Loot Box Value Decomposition

We start by quantifying the relative weight of the two roles of loot boxes in players' tastes. For this, we compare the value of the expected present discount utility flow under two scenarios. First, under the current game design, loot boxes increase current utility by providing users with an option to open a loot box today. This captures the direct utility of loot boxes. Second, they increase the future flow of utility by potentially affecting the inventory of divers. This increases the future likelihood of receiving win utility, as well as increases the likelihood that the user will stay in the game rather than leaving. This captures the functional value of loot boxes, which is realized in future periods.

Given the logit form of our choice model, the baseline future expected utility (up to a constant) takes the form of the "log-sum" of utilities attributable to each of the four actions that a player can take,

\[ \hat{V}_{\text{baseline}}(O) = \ln \left( \exp \left( u(a = 1) + \beta E_{R', \hat{O}', \epsilon'|O,a=1} V(O', \epsilon') \right) \right) \]

(18)

\[ + \sum_{a \in \{2,3\}} \exp \left( u(a = \hat{a}) + \beta E_{R', \hat{O}', \epsilon'|O,a=\hat{a}} V(O', \epsilon') \right) + \exp (u(a = 0)) \]

(19)

where \( u(a) \) correspond to the action-specific current period utilities outlined in Section 5. For the purposes of the decomposition exercise, we abstract away from the role of prices and currency by assuming loot boxes are free for the immediate period. \( V(O, \epsilon) \) is the true value function that is consistent with the full empirical model as defined in Equation 9, and the expectation is taken over the distribution of the next period states \( O' = \{R', \hat{O}'\} \) conditional on the current state \( O \) and action \( a \), where we write out \( R' \) apart from the rest of the states \( \hat{O}' = \{c, s, q, d, p^1, p^{11}\} \) since we adjust its transition probability in the utility decomposition.
We contrast this to the future expected utility of a scenario in which users do not have the option to open a loot box in the current period, 

\[ \tilde{V}_{\text{n.l.}}(O) = \ln \left( \frac{\exp \left( u(a_0 = 1) + \beta E_{R', \hat{O}', \hat{e}'|O, a_0 = 1} V(O', \hat{e}') \right) + \exp \left( u(a = 0) \right)}{\exp \left( u(a_0 = 0) \right)} \right) \]  

(20)

where the expected utility associated with having the option to open loot boxes has been removed. The difference between these two values \( \tilde{V}_{\text{baseline}} - \tilde{V}_{\text{n.l.}} \) represents the value that users get from an option to open one or eleven loot boxes in the current time period.

We now decompose the value of loot boxes into direct and functional mechanisms by shutting down only the functional value of loot boxes. For this, we shut down the expected change in inventory quality \( (R' = R) \) for the immediate period, which in turn affects future utility flow by changing the transition of states, and the players’ expectation of future expected rarity levels,

\[ \tilde{V}_{\text{n.f.}}(O) = \ln \left( \frac{\exp \left( \cdots \right) + \sum_{\hat{a} \in \{2, 3\}} \exp \left( u(a = \hat{a}) + \beta E_{R', \hat{O}', \hat{e}'|O, a = \hat{a}} V(O', \hat{e}') \right) + \exp \left( \cdots \right)}{\exp \left( u(a = 0) \right)} \right) \]  

(21)

The role of the direct utility of loot boxes in driving loot box openings can then be obtained as a ratio of the expected utility not explained by the functional component to the overall value of loot boxes,

\[ \frac{\tilde{V}_{\text{n.f.}} - \tilde{V}_{\text{n.l.}}}{\tilde{V}_{\text{baseline}} - \tilde{V}_{\text{n.l.}}} \]  

(22)

We weigh the expected values by the empirical frequency in which we observe players at the given states to present our results.

Table 8 shows the resulting decomposition for whales and non-whales. The first two columns ("overall") show the decomposition weighted by the users’ empirical distribution of states. Whales and non-whales have fundamentally different tastes for loot boxes, confirming our conclusions from the reduced-form estimates in Table 4. For whales, only 3% of loot boxes’ value comes from the functional mechanism, while for non-whales the functional mechanism accounts for almost 90% of loot boxes’ value. Part of this difference in the sources of loot boxes’ utility is explained by whales being more likely to play in the latter stages of the game, where the functional value is lower because the player already has a better inventory and is closer to finishing the game. For instance, at one of the first stages, stage 5 (columns 3 and 4), whales get 22% of loot box value from the functional mechanism, but only 4% at stage 50 (columns 5 and 6).

We further decompose the direct utility players get from loot boxes into a part explained by the state dependence in loot box consumption and a remainder part associated with the action of opening a loot box. For this, we extend the decomposition done in equation 22 and shut down the current period utility associated with the state dependence parameter. We find that state

Standard errors are computed using Bayesian bootstrap, with clustering (draws of observation weights) done at the stage level.

dependence accounts for a substantial share of the direct utility that players get from loot boxes, around 1/3 for whales and slightly less, around 23%, for non-whales. To the extent that state dependence serves as an upper bound on impulsive consumption, the estimates suggest that around 1/3 of the thrill value come from a behavioral bias that drives openings of loot boxes. We further examine the value of state dependence in loot box openings and its complementarity with the game in the counterfactuals below.

To confirm that our loot box value decompositions are not driven by the assumption of homogeneity of preferences within the groups of whales and non-whales, we redo the loot box value decomposition using the preference estimates with heterogeneity, presented in Table 7. Results are presented in Table 12 in Appendix A.4. We confirm that our main takeaways hold. The share of functional value in loot boxes is much smaller for whales (7.3%) than non-whales (66%), and state dependence accounts for 27%-42% of the direct value for players with a significant coefficient on the state dependence variable (clusters 2, 3, and 4).

Based on a snapshot – by turning off various drivers of value attributable to loot boxes for one immediate period – we conclude that direct thrill utility is an important source of utility for loot box opening, particularly for whales. This decomposition is a “partial effect” in that it does not reflect the effect on overall gameplay if consumer preferences or the gaming environment varied. Changing the environment likely affects in-game behavior and consequently the likelihood at which we see players in different game states. To better understand what consequences loot boxes have for the overall gameplay experience of consumers — and to understand what it means for game designers and policymakers — we turn to our counterfactual simulations.

9.2 Counterfactuals and Product Design Implications

Policymakers may be interested in regulating specific features of loot boxes and microtransactions more generally. A gaming company may seek to enhance engagement with the game by altering the possible outcomes of the game of loot boxes. These are questions of product design, and require an assessment of how these policy decisions affect the overall gameplay. In a series of simulations, we alter the design of the game – its difficulty – and the design of loot boxes, the

For cluster 1, the state dependence estimate in Table 7 is negative and noisy.
functional benefit that consumers get. We end with the counterfactual simulations that evaluate various policy actions proposed by consumer protection groups and regulators.

**Setup.** For any given counterfactual scenario and player type (e.g. non-whales), we draw simulated players from the empirical distribution of consumer types at the beginning of the game. For each scenario, we create a corresponding transition matrix and utility function. For instance, to simulate the outcomes in a more difficult version of the game, we decrease the probability that a player wins a stage and transitions to the next stage compared to the baseline transition matrix. Based on the transition matrix and utilities, we simulate the implied expected future utility function by iterating over the Bellman equation as in Rust [1987]. We then compute the implied conditional choice probabilities for any given counterfactual scenario, which we use to simulate how the players would play the game and open loot boxes. We start the simulation from stage 5, as the first few stages of the games were “tutorials” in which players were taught how to play the game, and are characterized by high exit rates which may not be attributable to the design of the stage game and of the loot box.

**Game design: changing the difficulty of the game.** In our first counterfactual, we simulate the engagement of users and the implied revenue if the gaming company were to make the game easier or harder. The difficulty of the game is one of the primary levers of game design that the company has, since the puzzle-solve nature of the game is the core mechanic in the game and its main stated attraction. The design of the stage game is likely to interact with the players’ preferences for loot box opening, which further showcases the argument that the role of loot boxes can only be assessed within the overall context of the game.

More specifically, we simulate how users would behave if the win probabilities of game stages were modified from the original game. We implement this by uniformly increasing or decreasing win probabilities of game stages by 10 percent increments, to make the game easier or more difficult. We place a lower bound of win probability at 10% so that the game is not prohibitively difficult such that it prevents players from making any progress.

Table 9 presents the resulting revenues and user engagement metrics. The first three columns show the expected revenue generated from opening loot boxes for real money – overall and split by non-whales and whales. We normalize the current revenue, under the baseline difficulty of the game, to unity. As the game becomes more difficult, the expected revenue the company can harness from the existing user base increases dramatically – from 100% to 223% if the win probability is decreased by 10 percent, and all the way to 2349% if the win probability is decreased by 50 percent. This increase in revenue is driven entirely by the expenditures of whales, who dramatically increase the number of rare loot boxes they open to still make progress in the game. In contrast, revenues from non-whales fall by around 30% when stages’ win probabilities are decreased by 50 percent points – since fewer non-whales engage with the game and keep playing.

Given such a large revenue upside from making the game more difficult, a natural question arises: Why does not the company implement this game design change? This design would

---

27 The sequential nature of the model makes solving this problem easier because it can be broken out into pieces. Namely, we use the simulated expected utility function from stage $s + 1$ as input into finding the expected utility function for states in stage $s$.

Easier

We simulate how players engage with the game when we uniformly increase or decrease win probabilities of game stages by 10 percent increments. Revenue is the average sum of payments made from opening rare loot boxes over the lifetime of a player. The number of times the player played the stage game includes the attempts the player lost. The weighted average value of each metric across non-whales and whales under the current design of the game is normalized to unity (presented in bold).

We target the preferences of whales and extract more value from them. However, by targeting the preferences of whales, the company will be providing an inferior product to all non-whales – who constitute the vast majority of the company’s players – and will decrease their adoption and engagement with the game. While non-whales bring only a tiny share of the game’s revenue, they generate direct network effects that increase the adoption of the game by players, including whales – e.g. because more popular games are higher in games’ rankings in the App Store and Google Play, generate more word-of-mouth, or create other positive peer effects. This reflects the value of “free” customers and the importance for firms to target them and balance out the revenue and growth objectives [e.g. Gupta et al., 2009, Lee et al., 2017].

To examine the effect of changes in the difficulty of the game on user engagement, the last six columns in Table 9 report the number of times an average user plays the stage game and the share of consumers reaching stage 20 – a benchmark for strong user engagement with the game, having completed the initial tutorial stages and becoming familiar with the game. Metrics for the baseline difficulty case are once again normalized to unity. The users’ engagement with the game drops prominently as the game becomes more difficult. Stage plays go down to 81% if the game’s complexity is increased by 10 percent, and to 28% if increased by 50 percent. In contrast, making the game easier increases the number of stage plays, although by a much smaller magnitude – making the game 50 percent easier increases the number of play occasions only by 6%. The metric of the shares of consumers at stage 20 – the last three columns – follows a very similar pattern, with the number of play occasions dropping by 79% if the game becomes 50 percent more difficult and increasing by 10% if the game becomes 50 percent easier.

Changes in user engagement are driven primarily by non-whales’ responses. If the win probability of the game decreases by 50 percent, non-whales decrease their engagement by 81% in terms of the number of play occasions and by 84% in terms of the share of players reaching stage 20. In contrast, the effect for whales is much smaller or even reversed. As the game
becomes more complex, the number of times whales play the game on average increases, by 4% if win probabilities increase by 10 percent and by 47% if by 50 percent. Such a positive relationship between the game’s difficulty and engagement for whales shows the complementarity between loot box openings and the gameplay. As the game is harder to complete, whales open more loot boxes and get better items. Concurrently they experience more impulsive loot box openings and ultimately play more. The last column shows that while whales make more play attempts, fewer of them make progress in the game: 2.5% fewer whales reach stage 20 if the win probability is halved.

Taking an overall look at Table 9, we can conclude that the current design of the game balances out the revenue and engagement objectives of the firm – a 10 percentage point decrease in win probability will lead to 123% higher revenues but also to a 19% lower stage play. A further increase in win probability by 10 percentage points will decrease revenue by 27% but increase engagement only by 5%. Whales and non-whales play different roles in this trade-off – whales are responsible for most of the revenue change, while non-whales are responsible for most of the engagement change.

**Loot boxes design: changing the variance of outcomes.** In our second counterfactual, we simulate outcomes under alternative loot box designs. One of the main controversial features of loot boxes is the randomness of loot box outcomes, making it in itself a “game of chance,” leading regulators to argue that loot boxes constitute gambling. While we cannot shut down the randomness of loot box outcomes entirely – unbundling loot boxes and offering a menu of items for purchase would require estimates of the direct values of items – we simulate counterfactual behavior of users under higher and lower variance of loot box outcomes.

To implement these simulations, we obtain new transition matrices corresponding to alternative loot box designs. In alternative scenarios, we keep constant the unconditional expected outcome of rarity levels, but either increase or decrease the odds of obtaining lower and higher rarity outcomes so as to increase or decrease the standard deviation of loot box outcomes by 30 and 50 percentage points. The effect of altering the variability of loot box outcomes is informative about the role of “chance” in loot boxes for the users’ gameplay. One observation, which we discuss concretely below, is that the expected return from opening loot boxes conditional on a player’s current inventory levels, is increasing in variance. Players only benefit if they receive divers that are of a higher rarity than what they have in their inventory. In other words, the role of “chance” in loot boxes is inherently associated with functional value as well.

Table 10 presents the simulated revenues and actions of players under different levels of the variability of loot boxes outcomes. The first three columns correspond to players with their current game and loot box preferences. The first thing that jumps out is that compared to changes in the game design presented in Table 9, changes in probabilities of loot box outcomes have a much lower impact on revenues and players’ behavior. For instance, the overall revenue decreases at most by 6% and increases at most by 30%, closely tracking the number of loot box openings. Interestingly, game revenue is higher under the smaller variability of loot box outcomes – e.g. if the standard deviation of loot box outcomes is 50% lower, the expected revenue is 30% higher and the number of rare loot boxes opened is 27% higher. This is despite a lower expected benefit of loot boxes under lower standard deviations of outcomes, as visualized.

We simulate how players would engage with the game if loot boxes were manipulated to result in higher or lower standard deviation in outcomes, with and without state dependence in loot box openings. Revenue is the average sum of payments made from opening rare loot boxes over the lifetime of a player. The number of times the player played the stage game includes the attempts the player lost. The weighted average value of each metric across non-whales and whales under the current design of the game is normalized to unity (presented in bold).
in Figures 20-21 in Appendix A.5. The reason for the counterintuitive response is because of whales, who open loot boxes not because of their functional value but due to their direct taste for loot boxes. Without functional value, it is harder to play the stage game, so whales open more loot boxes. In contrast, non-whales do not change their loot box opening behavior much, as they open very few loot boxes to begin with.

Columns 4-6 in Table 10 further highlight the importance of the state-dependent behavior in loot box consumption for whales. In these columns, we re-run the simulations setting the state dependence parameter \( \eta \) of players to zero. Results are drastically different compared to the baseline case. First, revenues drop significantly, by 91%, and no longer prominently change with loot box variability. This decrease in revenue is primarily driven by the decrease in the number of loot boxes whales open, which drops by more than 90%. The effect for non-whales is similar in direction but much smaller in magnitude – they start opening loot boxes 23% less – highlighting the higher importance of the direct value of loot boxes for whales. Interestingly, the effect of shutting down the state dependence parameter has different effects on non-whales and whales in terms of the volume of gameplay. Non-whales start to play the game a bit (3.1%) less, driven by the complementarity of the functional value of loot boxes, and gameplay. In contrast, whales play the game a bit more (2%), since now opening loot boxes is much less attractive to them and they did not get much functional value from them in the first place.

Overall, results in Table 10 suggest that the company will be better off if it reduces the variability of loot box outcomes – both revenue and players’ engagement will be slightly higher. This suggests that incentives of the company and regulators – who often argue against the randomness of loot box outcomes – are to some degree aligned. However, our counterfactuals cannot account for any changes in the direct value consumers due to changes in the loot box randomness making it hard to extrapolate our results to the case of gaming companies selling deterministic products.

Policies: Loot Box Ban and Spending Limits. Our results thus far suggest clear implications for the regulatory actions on loot boxes. On the one hand, we have shown that for most players – more than 98% of non-whales – there is a strong complementarity between the game and loot boxes, lending credibility to the video game companies’ arguments that the in-game value of loot boxes is important for players. This suggests that a blanket ban on loot boxes [e.g. like the one proposed by Forbruker Rådet 2022] will affect not only loot box openings but also the consumption and enjoyment of the main game itself by players. On the other hand, for a small but important minority of players – 1.5% of whales who bring the vast majority of firm profits – the core value of loot boxes is not their complementarity with the puzzle game but a direct thrill value from opening a loot box with uncertain rewards, closely resembling gambling behavior in other contexts. Such gambling-like behavior suggests that more targeted regulation of loot boxes, e.g. by creating strict spending caps, pre-committed limits, or by forcing players to take breaks from opening loot boxes, may be effective – supporting the proposals of Drummond et al. [2019], Close and Lloyd 2021, and Leahy 2022.

We evaluate the implications of these policy actions for our focal game by running a series of counterfactual simulations. First, we evaluate how a complete ban on loot boxes would alter players’ behavior and the welfare they get from the game. We simulate this scenario by removing
the option to open loot boxes (actions 2 and 3). Second, we evaluate a scenario where loot boxes are allowed only for in-game currency – so players cannot open any loot boxes by spending real money. We simulate this scenario by setting the price coefficient to negative infinity – so players can never open loot boxes if they do not have enough coins that were acquired through the organic gameplay. Finally, we evaluate the effects of implementing spending limits of different levels, varying from $100 to $500 per player per their lifetime. We simulate this scenario in a stylized way – players stay playing the game without any constraints, but once they hit the spending cap they cannot open more loot boxes using real money (but can keep using coins). The players are myopic regarding their “budget restriction” – they do not anticipate that they will hit a spending limit. This model reflects a scenario where players are not well informed about the spending limit and approximates a more complex model where players track how far they are from this budget constraint as an additional state variable.

Figure 10: Revenue and Consumer Surplus under Loot Box Bans and Spending Caps

Estimates of producer and consumer surplus by scenario and types of players. The overall surplus per (average) player under the current scenario is normalized to one (dashed line). We use an ex-post measure of consumer surplus – based on players’ realized path of actions – to decompose the surplus from playing the stage game and from opening loot boxes.

Figures 10 and 11 present the resulting revenue, consumer surplus, and the number of game-plays and loot box openings per average player and by types of players. The first bar in all subfigures corresponds to the current (baseline) scenario for an average player, with the total surplus (Figure 10) and the total number of actions (Figure 11) normalized to one. Producers get 7.4% of the total surplus in the form of revenue (abstracting away from fixed costs), with players getting 6.3% from opening loot boxes and the rest 86.3% from playing the game.\footnote{We use an ex-post measure of consumer surplus – based on players’ realized path of actions – to decompose the...}
Figure 11: Players’ Actions under Loot Box Bans and Spending Caps

(a) Overall  
(b) Non-Whales  
(c) Whales

Estimates of the number of consumer actions by scenario and types of players. The overall number of actions per (average) player under the current scenario is normalized to one (dashed line).

Splitting these average estimates for non-whales and whales, we see that non-whales (subfigure b in Figure 10) get the vast majority, 97.8%, of the total surplus from playing the game, with only 1.8% coming from opening loot boxes. The firm’s revenue from non-whales corresponds only to 0.2% of the total surplus generated. In contrast, whales (subfigure c in Figure 10) get only 39.3% of the total surplus from playing the game, but another 24.3% from opening loot boxes. Around 2/3 of the loot box welfare for whales comes from the state dependence in loot box openings. The company gets 36.3% of the total surplus through charges for loot boxes. We note, however, that while whales’ share of the surplus from gameplay is lower than this share for non-whales, in absolute values they get 2.7 times more utility from gameplay than non-whales (comparing blue bars in subfigures b and c in Figure 10 notice the scaling difference). This is both because they play the game 2.2 times more (green bars in subfigures b and c in Figure 11), as well as value playing the game more.

In the second set of bars (“No Loot Boxes”), we evaluate the effect of a complete loot boxes ban in our video game. Compared to the baseline scenario, the total welfare based on the tastes of an average player drops by 33.7%. This includes a drop to zero of revenue and consumer surplus from loot boxes – by construction, since loot boxes are now banned – but also a 23.2% drop in the surplus players get from playing the game itself. The decrease in surplus associated with gameplay comes only from non-whales (their welfare from gameplay drops by 25.4%), while whales are virtually unaffected. This result highlights a strong complementarity of the game surplus from playing the stage game and from opening loot boxes. Specifically, we track and take the (discounted) sum of utilities and realization of error draws to obtain the consumer surplus from the game.

Electronic copy available at: https://ssrn.com/abstract=4355019
and loot boxes that non-whale players experience, and confirms our conjecture above that a blanket ban on loot boxes will hurt the vast majority of consumers.

Next, in the third set of bars in Figures 10 and 11 (“No Paid Loot Boxes”), we evaluate a scenario where loot boxes are still in the game, but players cannot open any loot boxes by spending real money. Compared to the baseline scenario, consumer surplus from playing the game drops by 2.1%, and consumer surplus from opening loot boxes drops by 41.3%. A drop in consumers surplus from playing the game is driven entirely by non-whales players, while for whales players, consumers surplus from playing the game slightly increases (by 5.5%) under the ban of paid loot boxes – because such ban forces these players to replay hard stages more and get more play utility. In contrast, whales are responsible for the drop in consumer surplus from opening loot boxes – without an option to open paid loot boxes, they lose 50% of loot box openings surplus. By construction, the firm’s revenue (producer surplus) is zero.

In the last five bars across subfigures of Figures 10 and 11, we evaluate the effect of imposing spending caps of different levels, varying from $100 to $500 per player over their lifetime. In these scenarios, the actions and welfare of non-whale players are not affected, since none of these players cross the lowest threshold of spending $100 in our simulations. The consumer surplus of whales from playing the game is also very close to the baseline level. However, spending caps introduce large differences in how much surplus whales get from loot boxes, and how much revenue the firm collects. Under a $100 spending cap, whales get 84% of their consumer surplus from loot box openings, while the firm gets only 22.4% of the baseline revenue (24.3% of total baseline revenue). As the cap increases to $300, whales recover 98.3% of their baseline surplus from opening loot boxes, and the company recovers 61.1% of the baseline revenue from whales (62.2% of total baseline revenue). Finally, under a $500 spending cap, whales recover almost all, 99.9%, of their baseline surplus from opening loot boxes, and the company recovers 85% of the baseline revenue from whales (86.5% of total baseline revenue). In terms of actions (Figure 11), under the spending cap of $500 whales open 84.8% of loot boxes compared to the baseline scenario. This implies that the firm extracts almost all incremental surplus from loot boxes that are opened after the first $500 of expenditures of the player.

Overall, counterfactual simulations show that a blanket ban on loot boxes may be too stringent as a policy action. Apart from removing all surplus that players get from opening loot boxes, it significantly reduces consumer surplus from playing the game itself, due to the complementarity between loot boxes and gameplay that non-whales – the vast majority of players – experience. Banning only paid loot boxes could be a better middle-ground solution, recovering most of the consumer surplus from gameplay and around 50% of the consumer surplus from opening loot boxes. However, conditional on the development of the game, there is no producer surplus generated. This suggests that the company may not be able to recover its fixed costs of producing the game. To address this, policymakers can implement spending caps. Simulations show that spending caps are an effective tool in both further increasing the share of surplus players get from loot box openings (compared to the baseline) and in generating revenues for the company. A high spending cap (e.g. $300 or more) has close to no effect on the baseline consumer surplus but restricts the firm from profiting off of high-rollers, who give almost all their surplus to the firm in exchange for playing the loot box lottery.
10 Conclusion

In this paper we develop an economic framework to analyze and separate out two sets of tastes for lotteries in video games, a functional value of receiving virtual items that complement gameplay – the core in-game value of loot boxes as frequently argued by video game companies – and a thrill utility of opening loot boxes, which includes both normatively respectable entertainment value and openings driven by behavioral biases like impulsive consumption. We estimate consumer tastes for loot boxes in the context of a Japanese free-to-play puzzle game. Whales, 1.5\% of players responsible for 90\% of the firm’s revenue, open loot boxes primarily due to their direct value, with a significant share of this value being driven by state dependence in loot box openings. In contrast, the rest of the players enjoy loot boxes for their complementarity with the game, a functional value of items that players receive to make in-game progress. We use the estimates of consumers’ tastes to assess the impact of counterfactual game and loot box design on the firm’s revenue and engagement with the game.

Our results have direct implications for regulating loot boxes and other microtransactions that have a complementarity with gameplay. In a series of counterfactual simulations, we have shown that a blanket ban on loot boxes [e.g. like the one discussed by Forbruker Rådet 2022] is too stringent as a policy action. For most players – more than 98\% of non-whales – there is a strong complementarity between the game and loot boxes, meaning that a full ban will significantly reduce consumer surplus from playing the game itself. On the other hand, for a small but important minority of players – 1.5\% of whales who bring the vast majority of firm profits – the core value of loot boxes is not their complementarity with the puzzle game but a direct thrill value from opening a loot box with uncertain rewards, closely resembling gambling behavior in other contexts. We show that spending caps – restrictions on players that do not allow them to spend more than a certain amount of money in the game – allow players, both non-whales and whales, to recover the vast majority of surplus from the game while also restricting the firm from profiting off of high-rollers, who give almost all their surplus to the firm in exchange for playing the loot box lottery. Thus, our results support the proposals of Drummond et al. [2019], Close and Lloyd [2021], and Leahy [2022], who advocate for actions like spending caps, pre-committed limits, and forced breaks from opening loot boxes.

There are multiple avenues for future inquiry on the role of loot boxes for players and the optimal regulation of loot boxes. First, in designing policy, it would be informative to experimentally separate out mechanisms behind whales’ direct tastes for loot boxes – e.g. evaluate the extent to which the entertainment value from gambling, loot box outcomes variability, cues, impulsivity, and other behavioral mechanisms drive whales’ opening of loot boxes. Pinning down the exact mechanism or their relative weights will allow for more effective regulation to prevent whales’ potential over-spending on loot boxes. Second, to understand the effectiveness of existing policies, it would be useful to evaluate the effectiveness of existing self-regulations imposed by video game companies regarding loot boxes. For instance, in Japan, major gaming companies voluntarily agreed to prohibit behavioral targeting of loot boxes, such that consumers with different playing histories would see varying offers and odds of loot box outcomes. Third, many regulators’ concern with loot boxes stems from a disproportional exposure of minors to this gambling-like product. In our dataset, we do not observe any demographic information.
about players. Characterizing the difference in the nature of loot boxes’ value for kids can help to assess whether minors open loot boxes as a strategic part of the game or as an in-game slot machine.

These paths of inquiry require detailed information about how players engage with video games. We strongly support calls to provide researchers and regulators easier access to the algorithms and datasets describing the design and usage of loot boxes for independent research in the public interest [e.g. Forbruker Rådet, 2022]. We hope that this paper will serve as a starting point for more research on the value of loot boxes, including research based on loot box usage data that leverages players’ in-game choices and actions.

A.1 Additional Data Descriptives

Figure 12: A joint distribution of play and loot box openings across users

Based on a random sample of 10,000 users.

Electronic copy available at: https://ssrn.com/abstract=4355019
Figure 13: Distribution of Color of Divers.

Bars correspond to the shares of color observed among the corresponding sets of divers.

Figure 14: Win, Loot Box Opening, and Coin Spending Probabilities for Each Stage, only for Players who Reached Stage 173

Win rates are calculated by dividing the number of times a stage has been won, by the times the stage was attempted, using only sequential occasions of main stage plays. We use only observations of players who reached and won stage 173. Probabilities of opening at least one rare loot box and spending at least some coins are calculated by taking an average across players who are at a given stage.
Figure 15: Normalized Loot Box Opening and Coin Spending Probabilities for Each Stage

Probabilities of opening at least one rare loot box and spending at least some coins are calculated by taking an average across players who are at a given stage. We then normalize variable averages across stages to one to make visual comparisons simpler.
A.2 Effect of the Inventory Rarity on Win Probability ($\zeta$)

Here we use a more flexible regression specification to confirm that divers received from loot boxes do help improve the win probability of game levels. The vertical attribute of divers is rarity. We start by examining how the rarity of divers that players hold in their inventory affects the win probability, by estimating

$$\mathbb{1} (\text{win}_it = 1|D_{it}, a_{it} = 1) = \kappa_i + \kappa'_s + \sum_{r \in 1:6} \zeta'_r \mathbb{1} [\text{max} (\text{rarity}_{id} \in D_{it}) = r] + \eta X_{its} + \xi_{its} \quad (23)$$

where \(\text{max} (\text{rarity}_{id} \in D_{it})\) represents the highest diver rarity that is in the player’s inventory at time \(t\), and \(\eta X_{its}\) are additional controls, such as the number of times a player has played the game or opened loot boxes. \(\zeta'_r\) captures the effect of having a rare diver in the inventory at an average stage for an average player. Standard errors are clustered two-way, on the user and stage level.

Table 11 presents the estimates of \(\zeta'_r\). In Column (1) are estimates from the baseline specification, with the user and stage-level fixed effects but without additional controls \(\eta X_{its}\). Plays with a maximum diver rarity of one in the inventory, \(\text{max} (\text{rarity}_{id} \in D_{it}) = 1\), are taken as a baseline. When the maximum rarity is 2 or 3, there is almost no detectable change from the baseline – win probability decreases by 0.6-1.2 percentage points. However, when the maximum diver rarity is 4, 5, or 6, the average win probability increases by 6.4, 12.6, and 16.8 percentage points, respectively.

Columns (2)-(4) of Table 11 present the results after including the additional controls. The goal of these controls is to capture any evolution in players’ skill or inventory that is not captured by the user and stage fixed effects. The estimates show that our results are robust to these additional controls. Even after including both the count of loot boxes opened and plays by the user (Column 4), the probability of winning is low when the maximum diver rarity in the inventory is 1, 2, or 3. In contrast, the probability of winning is 2.5, 6.3, and 10 percentage points higher when the maximum diver rarity in the inventory is 4, 5, and 6, respectively.

A.3 Estimation of Transition Probability Matrices

We estimate the state transition probability matrices from the data, using a combination of frequency estimators and local approximations by linear models.

A.3.1 Rarity

For the rarity state $R_{it+1}$, we estimate transition probabilities using the frequency estimator conditional on the current action (play, open 1 loot box, open a pack of 11 loot boxes), whether the player lost last time ($q_{it}$), the current rarity ($R_{it}$), and stage ($s_{it}$). There are 17,748 unique state-action combinations; if the combination has less than 100 observations to estimate the transition probability (40% of unique states, accounting for 0.17% of observations in the data), we replace the estimate with the frequency estimator based on action-$q_{it}$-$R_{it}$-stage groups combinations, where stage groups are defined as stage group$_{it} = 1 \cdot I(s_{it} \leq 10) + 2 \cdot I(s_{it} \in \{10, 40\}) + 3 \cdot I(s_{it} \in \{40, 80\}) + 4 \cdot I(s_{it} > 80)$. Results are robust to using alternative thresholds since very few observations used in the estimation are affected by this approximation.

Figure 16 visualizes marginal distributions of the transition probabilities of rarity states, conditional on different actions. If users choose to play the game (action 1), the rarity of divers in their inventory changes very infrequently. In contrast, if users open one and especially eleven loot boxes there is a substantial transition to higher rarity states. The probability of an increase in the rarity of inventory is higher if the current rarity state of the inventory is lower.

A.3.2 Currency Stock

For the currency state $c_{it+1}$, we estimate transition probabilities using the frequency estimator conditional on the current action (play, open 1 loot box, open a pack of 11 loot boxes), prices of 1 and 11 loot boxes ($p_{1it}$ and $p_{11it}$), the current currency state ($c_{it}$), and stage ($s_{it}$). Since the price of a loot box only affects the currency stock when the corresponding loot box is opened, we do not condition on loot box prices when the player chooses action 1 (resulting in 8,996 unique states), condition on the price of one loot box when the player chooses action 2 (17,992 unique states), and condition on the price of eleven loot boxes when the player chooses action 11 (35,984 unique states).

Figure 17 visualizes marginal distributions of the transition probabilities of currency states, conditional on different actions. If users choose to play the game (action 1), their in-game currency almost never goes down, and either stays the same or increases by 1-2 coins. If users open one loot box, their currency decreases by 3 or 5 coins, depending on the price of the loot box. If the user’s currency is below the price of the loot box, with a high probability the currency stock goes to zero, reflecting the idea that the player pays with all the coins they have in the game and then contributes the difference by purchasing loot boxes with real money. Similarly, if the user opens a pack of eleven loot boxes, their currency stock very likely goes to zero.
Figure 16: Average Transition Probabilities of Rarity States, Across Actions

(a) Conditional on Action 1 (Play)

(b) Conditional on Action 2 (One Loot Box)

(c) Conditional on Action 3 (Eleven Loot Box)

Transition probabilities are averaged over stages $s_{it}$ and whether the player lost last time $q_{it}$.
Figure 17: Average Transition Probabilities of Currency States, Across Actions

(a) Conditional on Action 1 (Play)
(b) Conditional on Action 2 (One Loot Box)
(c) Conditional on Action 3 (Eleven Loot Box)

Transition probabilities are averaged over stages $s_{it}$ and loot box prices (for actions 2 and 3).
A.3.3 State Dependence

Transition probabilities for the state dependence variable, $d_{it}$, are trivial. State dependence gets assigned the value of one any time a player chooses to open a loot box in the previous period, as described by equation 4.

A.3.4 Loot Box Prices

We estimate transition probabilities for prices of 1 (11) loot boxes using the frequency estimator conditional on the current action (play, open 1 loot box, open a pack of 11 loot boxes), prices of 1 (11) loot boxes, and stage ($s_{it}$). Prices change only after the player opens the corresponding loot box – implying that prices for one loot box do not change when a user plays actions 1 and 3, and prices for eleven loot boxes do not change after actions 1 and 2. This means that we can estimate price transition probabilities only conditional on the current stage and the current price, leading to 348 and 696 possible states for prices of 1 and 11 loot boxes, respectively.

Figure 18 presents the estimates of probabilities of facing baseline prices for one and eleven loot boxes, $p_{11} = 5$ and $p_{111} = 50$. As the game progresses, players are getting more discounts on these prices.

A.3.5 Stage and Loss Indicator

Transition probabilities for the stage and loss indicator are determined by whether or not a player wins the stage. The win probability function is defined by equation 11 – we allow for flexible stage-and-loss-specific fixed effects and stage-and-loss-specific effects of rarity. We estimate equation 11 separately for whales and non-whales, and the fitted values of the regression are the estimates of win probabilities for each state. We set the small % of probabilities that fall slightly outside of the $[0, 1]$ interval (1.8% for non-whales and 2.2% for whales) to the bounds values.

Figure 18 presents the estimates of probabilities of winning the stage across various stages and rarity states. Figure 18a plots the probabilities against stages of the game; as the game progresses, the win probability declines, and every four stages there are discrete drops in the win probabilities corresponding to the “boss” levels. Win probabilities are slightly higher for whales than non-whales.

Figure 18b presents average win probabilities by the rarity stage of players’ inventories, by groups of stages. Across all groups, higher rarity inventory leads to higher stage win probability. However, the effect of the rarity state on win probability is more pronounced in the later stages of the game.
Figure 18: Probability to be Facing a Baseline Price of One ($p_{it}^1 = 5$) and Eleven ($p_{it}^{11} = 50$) Loot Boxes, Across Stages.

(a) Probability of Facing $p_{it}^1 = 5$

(b) Probability of Facing $p_{it}^{11} = 50$
Figure 19: Estimates of Probabilities to Win the Stage, Across Stages and Rarity States

Probabilities are the fitted values using the estimates of equation 11 for whales and non-whales, averaged across the states. Subfigure (a) plots the probabilities across stages for whales and non-whales. Subfigure (b) plots probabilities across rarity states by groups of stages, taking an average of estimates for whales and non-whales.

</table>

Standard errors are computed using Bayesian bootstrap, with clustering (draws of observation weights) done at the stage level.
A.5 Counterfactual Rarity Transition Probabilities

Figure 20: Counterfactual Transition Probabilities of Rarity States, Action 2 (One Loot Box Opened)

Transition probabilities are averaged over stages $s_{it}$ and whether the player lost last time $q_{it}$. 

A13
Figure 21: Counterfactual Transition Probabilities of Rarity States, Action 3 (Eleven Loot Boxes Opened)

Transition probabilities are averaged over stages $s_{it}$ and whether the player lost last time $q_{it}$.
