Abstract

Offices are social places. Employees and managers take coffee breaks together, go to lunch, hang out over drinks, and talk about family and hobbies. In this study, we show that employees' social interactions with their managers are advantageous for their careers and that this phenomenon contributes to the gender pay gap. We use administrative and survey data from a large financial institution. We estimate the impact of social interactions on career progression using quasi-random variation induced by the rotation of managers, along with the smoking status of managers and employees. When male employees who smoke transition to male managers who smoke, they take breaks with their managers more often and are subsequently promoted at higher rates. The smoker-to-smoker advantage is not accompanied by any differences in effort or performance. Moreover, we find that the male-to-male advantage is also only present among employees who work in close proximity to their managers, limiting the mechanism to channels requiring face-to-face interaction. The male-to-male advantage explains a third of the gender gap in promotions at this firm.

Keywords: gender, career, promotion, social interactions, networking.

*Corresponding author: zcullen@hbs.edu, Rock Center 310, Boston, MA 02163. We are thankful for excellent comments from several colleagues and seminar discussants. We are grateful for the invitations to present this work at UCSD, MIT, Berkeley-Econ, Berkeley-Haas, Yale Cowles Inaugural Labor and Public Conference, University of British Columbia, University of Southern California, Cornell, Princeton NLS-E, INSEAD, Columbia University Micro and Macro Labor, University of Zurich, Georgetown, Tufts University, University of Copenhagen, NBER Summer Institute, RIDGE Public Economics Conference, The World Bank, FAIR Institute, Harvard Business School, American Economic Association Annual Meetings and the Discrimination and Disparities intercollegiate seminar. We are especially thankful to Leonardo Bursztyn, Thomas Fujiwara and Amanda Pallais. The collaborating institution provided financial support for the research being conducted. Additionally, Zoe Cullen was a full-time, salaried employee at that institution while the research was being conducted. Dylan Balla-Elliott, Katherine Fang, Anh Nguyen, Giacomo Stazi, Andrew Kao, Aakaash Rao and Jenna Anders provided excellent research assistance.

1 Introduction

Workplaces are social places. Employees and managers often discuss all sorts of non-work related topics, such as sports, family, and movies. These personal interactions extend outside of office hours, such as during lunch, smoking, or coffee breaks. Through these interactions, employees form social bonds with their managers. In this study, we explore whether these social bonds influence employees' careers and whether they can help explain the gender pay gap.

Women have a harder time than men climbing the corporate ladder. Among U.S. corporations, 48% of entry-level employees are women, but female representation falls to 38% at middle-management, 22% at the C-Suite level, and 5% at the CEO level (McKinsey & Company, 2019). Improvement has been agonizingly slow over the last several decades. The gap in internal promotion rates accounts for the vast majority of the gender pay gap at the population level (Bronson and Thoursie, 2017). Not only is this unfair, it is inefficient, as misallocation of talent slows economic growth (Hsieh et al., 2019).

A growing literature has investigated what causes women to lag behind men in the corporate world. According to the "old boys' club" hypothesis, this gap arises in part because men can schmooze, network, and interact with more powerful men in ways that are less accessible to women.¹ This mechanism can create a self-perpetuating cycle: male managers promote a disproportionate share of male employees, who continue promoting other men.

Ample anecdotal evidence suggests that the old boys' club is real (Lang, 2011; Lee, 2014; Elting, 2018). For example, 81% of women say that they feel excluded from relationship-building at work, and many also feel excluded from after-work hours socializing (Gray and Barbara, 2013). Some women even believe that being able to use the men's bathroom would give them an advantage at work (Lee, 2014). Despite all the anecdotes, however, there is little quantitative evidence showing that the old boys' club exists. Studying social interactions and long-term outcomes presents many challenges; social interactions are rarely systematically recorded along side career outcomes, and the choice to socialize is typically endogenous, making causal inference challenging even when the data are available. In this study, we propose a quasi-experimental approach for testing this hypothesis and provide novel evidence based on data from a large financial organization.

We partnered with a large commercial bank in Asia (referred to hereinafter as *the firm*) with millions of customers, billions of dollars in assets and in revenues, and thousands of employees. The firm is typical in that female representation drops off at higher levels: 75% of entry-level employees are women, falling to 61% among middle managers, 25% at the C-Suite level, and 0% at the CEO and company board levels. Indeed, the gender gaps in pay and promotion rates at the firm are similar to those documented for other corporations in both developed and developing countries.

We have rich sources of administrative data spanning four years (2015-2018) and 14,736 unique employees, 1,269 of whom had a managerial role at some point. These records include the employees' pay grades, the managers to which they were assigned, as well as measures of effort and

¹ The term "old boys' club" was coined in reference to the British elite who attended certain public schools together. In current popular language, the term references the preservation of social elites in general.

performance. We also conducted a series of surveys to measure other aspects of the employees' lives, such as whether they take breaks with their managers, whether they know the manager's favorite sports team, and their smoking status.

First, we provide evidence on the role of social interactions in promotions. Employees may use interactions with their managers to gain their managers' favor and use these moments for self-promotion. During these interactions, employees may learn useful information, such as which tasks or training are more conducive to promotions. Managers may also learn more about their employees, identifying their effort, accomplishments and potential.

In the ideal experiment, we would flip a coin to decide which employees get to socialize more with their managers. While the ideal experiment is not feasible, we exploit quasi-experimental variation based on the rotation of managers. Managers rotate across teams and divisions as part of the requirement for managerial promotion. Upon rotation, they assume responsibility for all employees on the team. We conjectured that when an employee who smokes is assigned to a manager who also smokes, they will interact more because of shared smoking breaks. And, according to the schmoozing channel, the hypothesis is that the increase in social interactions will translate into higher promotion rates.

Our strategy for causal identification leverages the timing of manager transitions and comparisons between different types of transitions. For example, consider two teams, each managed by a non-smoking manager. One of these teams then transitions from the non-smoking manager to a smoking manager, and the other team transitions from the non-smoking manager to a different non-smoking manager. We can compare the outcomes of the smoking employees each month leading up to the manager transition date and each month after the transition. As both teams are affected by a manager transition, this design nets out the effect of the transition. The hypothesis is that transitioning to a smoking manager, relative to transitioning to the non-smoking manager, results in better promotion prospects for the smoking employees but has no effect (or little effect) on the promotions of non-smoking employees.

Using administrative and survey data, we identify the smoking habits of the employees and their managers. This part of the analysis is based on a sub-sample of males for whom we can infer smoking status: 2,907 unique employees and 588 unique managers.² The transition events are uniformly distributed across the four years, and they affect employees at every level of the organization. We conduct a series of empirical tests to confirm testimonies that the timing and team assignment of a manager rotation is as good as random. We show that the type of transition faced by an employee (e.g., from non-smoking to smoking manager) is uncorrelated with the observable characteristic of the employee, as well as with the characteristics of the in-coming and the out-going managers. Most importantly, the career progression of smoking and non-smoking employees follow parallel trends leading up to each type of manager transition.

Consistent with anecdotal evidence, we show a strong smoker-to-smoker advantage in the frequency of social interactions. In our survey data we measured the frequency of social interactions between employees and their managers by eliciting how often employees share their breaks with

² Since fewer than 5% of women smoke, female employees and managers are excluded from this part of the analysis. In contrast, 33% of male employees and 37% of male managers smoke.

their managers. After transitioning from a non-smoking manager to a smoking manager (relative to transitioning to another non-smoking manager), we find that smoking employees end up spending more than an additional quarter of their break time with their new managers, representing a 53% increase in shared break time. In contrast, there is no effect on non-smoking employees.

Next, we show that the increased social interactions due to co-smoking leads to significantly faster career progression. After a team transitions from a non-smoking manager to a smoking manager, smoking employees on that team are promoted more quickly. At 10 quarters after such a manager transition, smoking employees' were promoted 0.70 more pay grades (p-value = 0.002), equivalent to 15% higher salary, than smoking employees on a team that transitioned from a non-smoker manager to a different non-smoker manager.³ By contrast, the non-smoking employees experienced similar promotion rates regardless of whether they transitioned from a non-smoking manager to a smoking manager or from a non-smoking manager to another non-smoking manager. Our results are unchanged if we restrict to individuals who started smoking before the start of our panel, removing any dynamics in smoking status.

A natural question is whether these additional shared breaks lead to faster career progression due to productivity increases. For example, smoking managers might be better than non-smoking managers at motivating, monitoring and retaining smoking employees, or smoking employees may be more responsive to the directions of their smoking bosses or simply work harder under smoking managers than they would under non-smoking managers. However, we find no evidence that the co-smoking advantage can be explained by differences in retention or performance. When we estimate the effects of manager transitions on the probability of staying at the firm, we find point estimates that are close to zero, statistically insignificant, and precisely estimated. Moreover, when we estimate the effects of the manager transitions on measures of effort (the number of days worked and the number of hours spent in the office) and performance (the employee's own sales revenues), we find point estimates that are close to zero, statistically insignificant, and precisely estimated.

We bring some evidence to bear on the role of characteristics shared in common between a male employee and male manager more generally. We construct a variable that captures whether the employee and manager have at least one key shared trait in common: either they were born in the same province (true of 17% of pairs), or went to the same college (true of 11% of pairs), or were close in age (true of 30% of pairs). We focus on the same sample of workers and manager rotations as in the main smoking analysis, but we re-categorize manager transitions based on whether or not the manager and employee match on at least one of these characteristics. We estimate the effect of switching from a manager with whom the employee has no traits in common to one that matches on at least one trait, relative to switching from one manager with no traits in common to another another with no traits in common. While these attributes all have the potential to create a shared identity, we do not find evidence that they meaningfully increase the share of breaks taken together. We find a smaller increase in pay grade by the 10th quarter that is not statistically different from zero, and is less than one-half the magnitude of the smoker-to-smoker advantage. Taken together, shared characteristics (homophily) could contribute to an advantage but likely plays a minor role in

³ There is a linear relationship between the logarithm of salary and the pay grade. A 1-point increase in pay grade is associated with a 25% increase in salary ($= e^{0.227} - 1$). See Appendix A.2 for more information.

the smoker-to-smoker advantage.

Next, we explore whether social interactions contribute to the gender pay gap at this organization. In a nutshell, if male employees, relative to female employees, are more likely to interact with their male managers, that could give them a leg up in their career progression. Smoking together on work breaks would be one channel whereby men have disproportionately more opportunities to schmooze with each other, but there are many other shared activities that skew toward male proclivities. For example, smoking breaks are not only acceptable, but areas are specifically designated for such a purpose; we identified no equivalent activities that skew toward female proclivities (e.g. mothering/breast pumping rooms, nail salon breaks). Perhaps condoned break activities arise from a culture set by predominantly male leadership, but another reason why men may schmooze together more often could be due to differing time constraints on women with dependent family members (Juhn and Rubinstein, 2020; Cubas et al., 2019), or because men and women simply spend their time differently in and out of work and have different interests, for example, around sports (Bertrand and Kamenica, 2018).

We conduct the same event-study analysis of manager rotations discussed above but, instead of comparing male-only transitions from non-smoking to smoking managers, we compare transitions from female to male managers. This analysis is based on a 48-month panel of 14,736 unique employees (68% of whom are female), 1,269 unique managers (51% of whom are female) and 8,670 transition events. As in the case of our smoking analysis, we conduct tests to verify the plausibility of the assumption that manager rotations are quasi-random. Experiencing a particular manager transition event is unrelated to the characteristics of the employee, the incoming manager and the outgoing manager. And, most importantly, the career progression of the male and female employees follow parallel trends leading up to each type of manager transition.

We find that male employees are significantly more likely to share work breaks with their manager after transitioning from a female manager to a male manager (relative to transitioning from a female manager to another female manager). Female employees, on the contrary, are equally likely to spend breaks with male and female managers. Coincidentally, the magnitude of the boost in social interactions when a male employee is paired with a male manager is similar in magnitude to the boost that male smoking employees experience when they transition to a male smoking manager: male employees share 35% more breaks with their manager when assigned a male manager.

In addition to interacting more with their male managers, we find that those male employees are promoted more quickly, following the same pattern in timing and magnitude as smoking employees paired with smoking managers. At 10 quarters after a male employee transitions from a female to a male manager, male employees' pay grades were 0.60 points (p-value = 0.003) higher than those of male employees who transitioned from a female manager to a different female manager. This 0.60 point increase in pay grade is equivalent to a 14.6% increase in salary. By contrast, female employees experienced similar promotion rates regardless of whether they transitioned from a male manager to a female manager or from a male manager to another male manager, additional evidence that homophily alone does not necessarily translate into a career advantage.

Since the sample used for the analysis of manager gender is much larger, we can provide a

number of additional robustness checks. First, we analyze the reverse transition.⁴ In the baseline results presented above, we look at employees who “lose” a male manager (i.e., transitioning from a male manager to a female manager versus transitioning from a male manager to a different male manager). Next, we look at employees who “gain” a male manager (i.e., transitioning from a female manager to a male manager versus transitioning from a female manager to a different female manager). The expectation is that the effects of gaining a male manager should be roughly a mirror image the effects of losing a male manager, in terms of both timing and magnitude. This is a sharp test, in the sense that the coefficients are identified by a disjoint set of transition events and thus there are no mechanical reasons why the results should mirror each other. Indeed, we find that the effects of losing a male manager are in the opposite direction of the effects of gaining a male manager, and they are similar in terms of timing and magnitude. Male employees who transition to a female manager (relative to transitioning to another male manager) end up with a pay grade that is 0.30 points lower at 10 quarters later (p-value = 0.032), whereas the evolution of pay grades for female employees is unrelated to the manager’s gender.

The second robustness test is based on placebo events. We reproduce the whole analysis, but instead of focusing on gender as the relevant characteristic of managers and employees, we focus on a characteristic that we know *ex ante* should not be relevant: whether someone was born on an even or odd date. In other words, we would not expect that managers born on an odd date would be beneficial to the careers of their subordinates. We reproduce the whole event-study analysis, but instead of slicing the data based on manager and employee genders, we focus on their birth dates. This test rules out mechanical reasons why our event-study framework would generate spurious effects, and allows us to assess whether our standard errors are adequate. As expected, we find that the estimates are close to zero, statistically insignificant, and precisely estimated.

We define the male-to-male advantage as the effect of male managers (relative to female managers) on the careers of male employees (relative to female employees). Our preferred estimate, based on the transitions in both directions, indicates that the male-to-male advantage in pay grade is highly statistically significant (p-value<0.001) and economically large (0.65 pay grades at 10 quarters after the event). In back of the envelope calculations, we estimate that removing the male-to-male advantage would reduce the gender gap in pay grades by 40%.⁵

We show that the male-to-male advantage also cannot be explained by differences in retention or performance. There are no corresponding differences in the probability of staying at the firm, we find point estimates that are close to zero, statistically insignificant, and precisely estimated. When we estimate the effects of the manager transitions on measures of effort (the number of days worked and the number of hours spent in the office) and performance (the employee’s own sales revenues), we find point estimates that are close to zero, statistically insignificant, and precisely estimated.

While shared smoking breaks, concentrated among men, cannot by itself explain the entire

⁴ We include the reverse transitions for smokers in Appendix A.1, however, given the infrequency of smoker-to-smoker manager transitions, the critical comparison group, the event study lacks the required power to interpret the point estimates.

⁵ For more details, see Section 7.1.

male-to-male advantage, we provide suggestive evidence that the male-to-male advantage operates through the wider set of social interactions between employees and their managers. If driven by socialization, the male-to-male advantage should be stronger when manager and employee pairs work in close physical proximity; by contrast, the effects should be smaller, or even null, when the manager does not work in physical proximity to the employee. We categorize positions by the physical proximity with the manager using administrative data on office locations as well as survey data asking employees if their managers work in physical proximity. Consistent with the social interactions channel, we find that the male-to-male advantage is large and statistically significant when the managers and employees work in close physical proximity but close to zero and statistically insignificant if they do not work in close proximity.⁶

Next, we provide suggestive evidence that gender norms may be a mediating factor of the male-to-male advantage. For example, in more chauvinistic contexts, male managers may be more prone to promoting their male employees (Jayachandran, ming). We gain some traction on this question using variation in geography of units and the hometown provinces of their employees. Based on prior research in the German context, we expect the northern regions to have more equal gender norms around roles at work due to longer spans of communist rule (Boelmann et al., 2021). Indeed, the gender gap in the labor force participation is three times as large in the southern regions than in the northern regions.⁷ Among World Value Survey respondents⁸, there is a 12 percentage point gap (or 31% difference) in the share of men who agreed with the statement that men are better business executives than women. Using the firm's pay grade data, we find that the gender pay gaps is 39% higher in the southern units than in the northern units (1.1 pay grade gap in the south versus 0.8 pay grade gap in the north, p-value of the difference=0.016).

This study is related to various strands of literature. Most important, it is related to a literature on the role of social interactions at work. Despite the universality of socializing in the workplace, relatively little is known about the returns of these personal interactions and whether these returns differ by gender. Cai and Szeidl (2018) provide experimental evidence that increasing the connections between business owners can increase firm productivity. There is also evidence of spillovers between business school classmates and executives (Shue, 2013; Lerner and Malmendier, 2013; Agarwal et al., 2016; Field et al., 2016).⁹ There is evidence that the managers' social skills affect employee turnover (Hoffman and Tadelis, 2021). In the context of fruit-pickers, managers with fixed pay will favor workers with whom they share a connection, to the detriment of firm productivity (Bandiera et al., 2010, 2009). And in the context of politics, public officials may capitalize on their political and personal networks to gain influence (Cruz and Tolentino, 2019; Xu, 2018; Voth and Xu, 2021)

We contribute to this literature by providing novel evidence on the career and productivity con-

⁶ We replicate the analysis using propensity score matching to maintain balance across job characteristics in high and low proximity positions. Results after re-weighting are nearly identical.

⁷ These figures were calculated from the most recently available census data (from 2009).

⁸ Our sample is restricted to those who look similar to employees in our firm based on education and urbanization.

⁹ Another related study is Lleras-Muney et al. (2019), showing that friendships accumulated during high school can have lasting impacts on labor market outcomes. Also, Mengel (2015) use a laboratory experiment to show that men and women both engage in networking but men develop closer connections.

sequences of social interactions in the corporate world. This is a context for which there is abundant anecdotal evidence on the importance of social interactions and its effects on the gender pay gap, yet little quantitative evidence. The lack of evidence is probably due to data challenges (e.g., personal interactions are difficult to measure and also sensitive information) as well as challenges with causal identification (e.g., social interactions are highly endogenous). We address both of these challenges. First, we provide causal evidence based on quasi-experimental variation in the gender and smoking habits of the managers. Furthermore, we collected unique sources of administrative and survey data about social interactions and physical proximity in a real corporation that spans culturally distinct regions.

Our paper more broadly contributes to the large literature on the gender wage gap (Goldin, 2014). There is a consensus that the majority of this gap is due to differences in promotion rates (Bertrand, Goldin, and Katz, 2010; Manning and Swaffield, 2008; Goldin, Kerr, Olivetti, and Barth, 2017). By one careful account, the gap in internal promotion rates can account for approximately 70% of the gender pay gap by the age of forty-five (Bronson and Thoursie, 2020). Several explanations have been provided for these differences in promotions.¹⁰ Most related to our study, Kunze and Miller (2017) examine data from a private firm in Norway and find a positive association between the share of male managers at the establishment level, and a gender gap in the promotion rate of employees.¹¹ Other studies evaluate the role of gender of superiors in the education industry, with mixed results. On the one hand, male teachers in public schools are more satisfied with their jobs and more likely to remain working at a school if they have a male, rather than female, principal (Grissom, Nicholson-Crotty, and Keiser, 2012; Husain, Matsa, and Miller, 2018). On the other hand, female referees and female committee members in academia do not increase the odds of acceptance of female-authored papers or promotion of female candidates (Bagues, Sylos-Labini, and Zinovyeva, 2017; Card, Dellavigna, Funk, and Iriberry, 2020; Kim, 2020).¹²

We contribute to this literature in several ways. First, we provide causal estimates with the use of quasi-experimental methods, and we examine a range of career and performance outcomes. Second, we provide novel evidence about a specific mechanism, social interactions, for which there is abundant anecdotal evidence yet it has been largely ignored in the literature on the gender pay gap.

The rest of the paper proceeds as follows. Section 2 summarizes the research design and our econometric specification. Section 3 presents the institutional context for this study and describes

¹⁰ Some examples include the marriage market incentives (Bursztyn, Fujiwara, and Pallais, 2017), cultural norms (Bursztyn, Fujiwara, and Pallais, 2017; Alesina, Giuliano, and Nunn, 2013; Jayachandran, 2013), recognition for group work (Sarsons, 2017; Isaksson, 2019; Sarsons et al., 2021), differences in aspirations and performance (Azmat and Ferrer, 2017), the child penalty (Schönberg and Ludsteck, 2014; Bertrand et al., 2010; Kleven et al., 2019; Kuziemko et al., 2018), preference for flexible hours (Wasserman, 2018) and household work more generally (Cortés and Pan, 2019).

¹¹ A related literature studies whether female representation at the very top of the firm, such as owners, CEOs, and chairs, can affect the female employees working at those companies (Bell, 2005; Bertrand et al., 2019; Cardoso and Winter-Ebmer, 2010; Dalvit et al., 2020; Flabbi et al., 2019).

¹² Other related studies look at gender roles among peers instead of among managers (Dahl et al., 2021; Hill, 2017; Stoddard et al., 2020) and at the role of other demographics besides gender, such as race (Mas and Moretti, 2009; Bandiera et al., 2010; Giuliano et al., 2011; Hjort, 2014; Glover et al., 2017).

the data. Sections 4 and 5 present the results. Section 7 provides additional discussion of the results and Section 8 concludes.

2 Research Design

2.1 Conceptual Framework

Our analysis revolves around the effects of manager characteristics on the subsequent career progressions of their employees. For example, we want to measure whether smoking employees fare better after transitioning from a non-smoking to a smoking manager and whether male employees are promoted faster when they transition from a female to a male manager. To estimate these manager effects, ideally we would randomize employees to their managers. As this type of experiment is not feasible, we instead exploit naturally occurring rotations in manager assignments within the organization. Rather than relying exclusively on testimony that these manager rotations are as good as random, we test that assumption by examining the parallel trajectories of employees who undergo different transitions along a wide range of behaviors using event-study analyses. The formal econometric framework for the event-study analysis is provided below.

2.2 Effects of Manager’s Smoking Habits

Let $y_{i,t}$ be a generic outcome, where the subscripts i and t denote employees and time, respectively. The main outcome in our analysis is the employee’s pay grade, but we also consider other outcomes such as firm exit, effort, and performance.

We compare two teams, each led by a non-smoking manager. One team transitions to a smoking manager, and the other team transitions to a different non-smoking manager. We compare the differential effects of the transitions for smoking employees and for non-smoking employees separately. The prediction is that transitioning to the smoking manager should benefit the subsequent career of the smoking employees, whereas it should not affect, or less prominently affect, the careers of the non-smoking employees. Let $D_{i,t}^j$ denote the traditional event-study variables that indicate the periods leading up to and following a transition event. For example, $D_{i,t+e}^j$ is an indicator variable that equals 1 if individual i experiences an event of type j in period $t + e$.

$$y_{i,t} = \sum_{j \in J_S} \sum_{e \in \mathcal{E}} \beta_{j,e}^S \cdot S_i \cdot D_{i,t+e}^j + \sum_j \sum_e \beta_{j,e}^N \cdot (1 - S_i) \cdot D_{i,t+e}^j + \gamma_i + \eta_{i,t} + \delta_t^S + \delta_t^N + \varepsilon_{i,t} \quad (1)$$

where J_S is the set of the types of manager transitions $J_S = \{N2S, N2N, S2N, S2S\}$. For instance, $N2S$ denotes a transition from a non-smoking manager to a manager who smokes.

We define single-difference and double-difference estimates for these manager transitions. For example, the following single-difference estimate measures how smoker employees react to gaining a smoker manager (i.e., transitioning from a non-smoker manager to a smoker manager, relative to transitioning from a non-smoker manager to another non-smoker manager): $\beta_{N2S,e}^S - \beta_{N2N,e}^S$.

Likewise, we can use the following double-difference estimate to measure the smoker-to-smoker advantage: $(\beta_{N2S,e}^S - \beta_{N2N,e}^S) - (\beta_{N2S,e}^N - \beta_{N2N,e}^N)$.

The set \mathcal{E} , the event-study window, spans from 30 months before the event to 30 months after the event (this time window is due to the length of our panel data). We include the usual absorbing dummies at extremes of ≤ -31 and $\geq +31$ months (Stevenson and Wolfers, 2006). In the event-study graphs, we aggregate these monthly coefficients to the quarterly level for ease of presentation. The omitted categories in \mathcal{E} are the three months prior to the event (i.e., -3, -2, and -1 months), aiding our visual depiction at the quarterly frequency. This baseline specification includes employee fixed effects (γ_i), manager fixed effects ($\eta_{i,t}$) and smoking status-specific month effects (δ_t^N and δ_t^S). In this study, we always use two-way clustering of the standard errors at the team and manager levels.

To isolate the impact of a change in manager smoking status from a change in manager more generally, we always compare employees undergoing manager transitions where one of those transitions results in a change of manager smoking status and the other does not. For example, we compare the effects of transitioning from a non-smoking manager to a smoking manager versus the effects of transitioning from a non-smoking manager to a different non-smoking manager. In the case of smoking employees, the object of interest is $\beta_{N2S,e}^S - \beta_{N2N,e}^S$ where e indicates the time since (or until) the transition date. In the case non-smoking employees, the corresponding object of interest is $\beta_{N2S,e}^N - \beta_{N2N,e}^N$. Hereinafter, we refer to these objects as the *single-differences*, because they are differences between types of transitions.

What we capture with the single-difference estimates is the impact of receiving a smoking manager relative to the impact of receiving a new non-smoking manager. However, we are ultimately interested in whether the effects of manager smoking status differ for smoking and non-smoking employees. For example, if smoking managers increase pay grades for smoking and non-smoking employees alike, that would not constitute evidence of a smoker-to-smoker advantage. Thus, we must take the difference of the single-difference estimates between smoking and non-smoking employees: $(\beta_{N2S,e}^S - \beta_{N2N,e}^S) - (\beta_{N2S,e}^N - \beta_{N2N,e}^N)$. A positive difference would be consistent with a smoker-to-smoker advantage. We refer to these estimates as the *double-differences*, because they take differences first with respect to types of transitions and second with respect to the employee's own smoking status.

The key assumption is that, prior to the transitions, smoking and non-smoking employees were on the same pay-grade trajectories irrespective of their upcoming transition. The event-study framework provides a natural test of the identifying assumption: we can assess the evolution of the outcome in each month before the date of the transition to confirm if the trends were truly parallel before the event date.

When interpreting the event-study results, there are a few features to keep in mind. First, our estimates measure a reduced form effect of an increased but likely transitory exposure to a given manager. As time goes by, many reasons can explain why an employee ends up with a manager of a different smoking status. For example, the employee may be promoted to a different position and assigned a manager of a different smoking status, or the employee may move laterally to another team with a manager of a different smoking status. In this sense, our estimates will under-estimate the effect of the manager's smoking status: if the employee were to stay with the new manager

forever, the effects would presumably be even stronger. In practice, this is a minor detail, as we find transitions to be persistent over time.

2.3 Effect of Manager’s Gender

We also directly evaluate a gender shock to social interactions. The transition between two managers can result in one of four different types of gender transitions. Let J_G denote the set of these types: $J_G = \{F2M, F2F, M2F, M2M\}$, where $F2M$ denotes a transition from a female manager to a male manager, $F2F$ denotes a transition from one female manager to another female manager, and so on. We use a variant of the same specification to identify the smoker events, based on a larger sample including males and females. Again, the event-study specification is identical to that in equation (1), except that the smoking status is replaced everywhere by the gender status.

The event-study regression relates the outcome variable to the event-study dummies:

$$y_{i,t} = \sum_{j \in J_G} \sum_{e \in \mathcal{E}} \beta_{j,e}^F \cdot F_i \cdot D_{i,t+e}^j + \sum_{j \in J_G} \sum_{e \in \mathcal{E}} \beta_{j,e}^M \cdot (1 - F_i) \cdot D_{i,t+e}^j + \gamma_i + \eta_{i,t} + \delta_t^F + \delta_t^M + \varepsilon_{i,t} \quad (2)$$

Note that we interact the event-study dummies with a gender indicator (F_i) to estimate event-time coefficients for men ($\beta_{j,e}^M$) and women ($\beta_{j,e}^F$) separately.

Due to the significantly larger sample size, manager gender transitions provide an additional validation check based on the principle that transitions in the opposite direction should result in approximately the opposite effects.¹³ We discussed the effects of “gaining” a male manager (i.e., what happens when an employee transitions from a female manager to a male manager, relative to what would have happened if the employee transitioned from a female manager to another female manager). Likewise, we can measure the effects of “losing” a male manager (i.e., what happens when an employee transitions from a male manager to a female manager, relative to what would have happened if the employee transitioned from a male manager to another male manager). The expectation is that the effects of gaining a male manager should roughly mirror the effects of losing a male manager in terms of timing and magnitude. Because these coefficients are identified by a disjoint set of transition events, there are no mechanical reasons why the results should mirror each other.

To maximize statistical power, we estimate the average male-to-male advantage using all four types of gender transitions. That is, we average the double-difference estimates from “gaining” a male manager and the (negative of) the double-difference estimates from “losing” a male manager: $\frac{1}{2}\{(\beta_{F2M,e}^M - \beta_{F2F,e}^M) - (\beta_{F2M,e}^F - \beta_{F2F,e}^F) - [(\beta_{M2F,e}^M - \beta_{M2M,e}^M) - (\beta_{M2F,e}^F - \beta_{M2M,e}^F)]\}$. We refer to this object as the *dual-double-difference*.

¹³ While we have 939 events for employees undergoing a transition from a non-smoking to another non-smoking manager, we only have 276 events for employees undergoing a transition from a smoking to another smoking manager. As a result we are unable to carry out the same validation check in our analysis of smokers.

2.4 Placebo: Effects of Manager’s Birthday-Evenness

As a robustness check, we reproduce the analysis, but instead of focusing on smoking status or gender as the relevant characteristic of managers and employees, we focus on a characteristic that we know *ex ante* should not be relevant: whether someone was born on an even or odd date. This placebo test is designed to rule out mechanical reasons why our event-study framework would generate spurious effects. This placebo analysis can also be used to assess whether our standard errors are adequate: e.g., if we found statistically significant coefficients, it would suggest that the inference is misleading. Let O_i be an indicator variable that equals 1 if the employee was born on an even day and 0 otherwise. The regression of interest is identical to the main specification from equation (1), except that gender is replaced everywhere by the birthday-evenness:

$$y_{i,t} = \sum_{j \in J_E} \sum_{e \in \mathcal{E}} \beta_{j,e}^O \cdot O_i \cdot D_{i,t+e}^j + \sum_{j \in J_E} \sum_{e \in \mathcal{E}} \beta_{j,e}^E \cdot (1 - O_i) \cdot D_{i,t+e}^j + \gamma_i + \eta_{i,t} + \delta_t^E + \delta_t^O + \varepsilon_{i,t} \quad (3)$$

where J_E is the set of manager transitions $J_E = \{E2O, E2E, O2E, O2O\}$: $E2O$ denotes a transition from a manager with an even birthday to a manager with an odd birthday, and so on. We identify analogous single-difference, double-difference, and dual-double-difference estimates for these placebo events. For example, the following single-difference estimate measures how the odd-birthday employee reacts to gaining an odd-birthday manager (i.e., transitioning from an even-birthday manager to an odd-birthday manager, relative to transitioning from an even-birthday manager to another even-birthday manager): $\beta_{E2O,e}^O - \beta_{E2E,e}^O$. We use the following double-difference estimate to measure the odd-to-odd advantage: $(\beta_{E2O,e}^O - \beta_{E2E,e}^O) - (\beta_{E2O,e}^E - \beta_{E2E,e}^E)$.

In the results section, we present an additional placebo test measuring if the transitions in the manager’s gender affect even-birthday and odd-birthday employees differentially.

3 Institutional Context and Data

3.1 Institutional Context

We collaborated with a private commercial bank in Asia. To keep the identity of the firm secret, we refrain from providing exact information about its characteristics. This bank spans several culturally distinct regions and has millions of customers, billions of dollars in assets and in revenues, and thousands of employees. Although we do not claim that this firm is representative of all firms in the world, we have evidence that this is not an extreme context. According to the World Bank (2016), the share of men and women who smoke around the world is 35% and 6% respectively; this breakdown is identical to smoking rates at the firm we study. Among OECD member countries, 29% of men smoke and 18% of women.¹⁴ As far as work breaks and social interactions are concerned, the firm maintains a general policy of managerial discretion during the work day, allowing the manager to decide whether and how to coordinate lunch breaks and other midday breaks. The social

¹⁴ These data are collected by the World Health Organization and made available by the World Bank in its Global Health Observatory Data Repository. Accessed May 2021.

norms at the firm level include taking time out of the workday to celebrate employee birthdays, the firm's birthday, international women's day, and the new year. The American phrase "sharing is caring" is a popular phrase used by employees to capture the general sentiment that personal news are welcome.

The gender gaps at this organization are average by U.S. standards. The gender pay gap at this firm (23%) is close to the average of similar-sized firms in the financial sector in the United States (31%).¹⁵ The firm is typical in that men and women in a given position get paid similarly. The bulk of the gender pay gap thus is due to differences in positions among men and women. For example, 75% of firm employees at the entry-level are female, and that fraction falls to 61% in middle management, 25% at the C-Suite level, and 0% at the CEO level. Data for U.S. corporations suggest a similar drop from 48% of female employees in entry-level positions to 38% in middle management, 22% in C-Suite positions, and 5% in CEO positions (McKinsey & Company, 2019). Like Bank of America,¹⁶ our setting is majority female due in large part to service positions at low levels.

When looking at the regions where the firm operates as a whole, the gender gaps are similar to those in the United States. For example, the gender gap in labor force participation (8.5%) is comparable to the one in the United States (13.2%).¹⁷ According to survey data, the gender norms also are not unusual. For example, data from the 2006 World Value Survey suggest that 12% of women in the firm's country describe work as unimportant or of little importance, and the respective share is 19% in the United States. In Section 5.5, we leverage variation in gender norms across culturally distinct regions where the firm operates to examine the mediating role of local norms.

3.2 Administrative Data: Pay Grade

We collaborated with different divisions of the organization to create a centralized and anonymous database of every employee in the firm. We constructed a monthly panel spanning four years, from January of 2015 to December of 2018. This panel includes 14,736 unique employees, 1,269 of whom have been assigned to a manager role at some point. Finally, 64% of the employees are female, and 49% of the managers are female.

Our main outcome variable is pay grade. This outcome ranges from 41 to 66 and is the best measure of the vertical career progression in the organization, and the metric over which managers have the most direct input.¹⁸ Indeed, employees commonly use pay grades as a measure of their rank in the firm in conversations with other employees. An increase in pay grade is associated with a

¹⁵ Results based on wage rates for men and women working in the financial sector in firms with over 1,000 employees, as reported in Yildirmaz et al. (2019).

¹⁶ about.bankofamerica.com/en/making-an-impact/advocating-social-justice

¹⁷ Labor force participation data come from the World Bank Databank and International Labour Organization ILOSTAT database. These 2017 figures are the most recent for which male and female labor force participation data are available in both countries.

¹⁸ HR personnel often carry out the precise salary negotiation within the range determined by pay grade, using market benchmark data.

promotion, or increase in responsibilities. Conditional on an increase in pay grade, there is an 84% chance of a change in position title; in comparison, there is a 1% chance of a change in position title when there is no pay grade increase. Variation in pay grade suggests that, consistent with anecdotal evidence, there is ample opportunity for upward mobility in the firm. Among the 7,622 employees who worked at the bank during the full sample period of four years, 50% experienced at least one pay grade increase, and 16% experienced more than one increase.

Due to the sensitive nature of the data, we do not have the exact compensation details for the whole sample of employees. However, for a different project on a different topic (Cullen and Perez-Truglia, 2021), we have a cross-section of the pay grades and base salaries of employees in a given month (March of 2017). According to these data, there is a very precise linear relationship between the logarithm of salary and the pay grade (results presented in Appendix A.2). The slope of the relationship (0.227) indicates that a 1-point increase in pay grade is associated with a 25% increase in salary ($= e^{0.227} - 1$). The R^2 of the regression (0.83) also indicates that pay grade explains the vast majority of variation in salaries.

Although the setting involves employees competing for promotions, employees are not necessarily competing with their teammates. There are no limits on the number of employees on a team that can be promoted, and different employees from the same team may seek promotions into different positions. Indeed, these employees compete for promotions with employees from other teams in the firm, and as the company routinely hires new employees, they also implicitly compete with outside candidates.¹⁹

3.3 Other Outcomes: Attrition, Effort, and Performance

We know the dates when the employees join and exit the company, which allows us to construct a dummy variable for employee attrition. We also have some measures of effort and performance. The first measure of effort is the number of days worked. We construct this measure using data from the human resources divisions on absences. We subtract the number of absences, including parental leave, sick days, and vacation days, from the total number of workdays in the month. We use an additional measure of effort to complement the administrative data: the number of hours spent in the office. However, we measure this outcome only for employees working in the headquarters offices (29% of the sample), as those employees clock in and out using an electronic card-swipe system that is strictly enforced by security personnel. We use these time stamps to calculate the average number of hours in the office. Finally, we measure sales performance based on individual employees' sales revenue. The bank uses an official formula to aggregate an employee's sales across all products (e.g., credit cards, loans, mortgages) by mapping each product to the expected revenue generated from the sale. We use these data to construct a monthly sales performance index.

¹⁹ More specifically, there is both a high employee turnover (12.5% yearly) and growth in the number of employees (5.9% yearly).

3.4 Manager Assignments

Because a single employee may consider more than one person to be his or her manager, we identify the most relevant manager as the one who has the most power over the employee. We use longitudinal data from the firm’s organizational chart to link each employee to a manager in each month that the employee appears in the sample. The employee-manager assignment is constructed using a simple, two-step algorithm: identify the employee’s team, and then identify the “director” of that team.²⁰ To validate our manager assignments, we conducted a survey of the sales and distribution division (described in Section 3.6). We asked employees to identify the managers who “have directly influenced your key performance indicator and pay grade.” In the month of the survey, December 2017, 91% of the managers we identify using the organization chart also are reported by the employees to be their managers.²¹

The managers tend to be significantly above their subordinates in the firm’s hierarchy. For example, the modal (mean) distance between managers and their employees is 5 (5.3) pay grades. The manager typically can influence the careers and daily lives of the employees in various ways. Most importantly, the manager provides key input in decisions to promote employees. Even if the employee is not promoted, the manager still provides input that influences employee’s raises and bonuses. The manager also has discretion to distribute workload across team members. Even if the work hours are rigid, such as for tellers, the manager still has latitude to approve leaves of absences or late days.

3.5 Manager Transitions

In this study, we focus on manager transitions that result from the reassignment across teams as part of managerial rotations. We are not considering transitions that result from employee promotions to another team, or employee transfer requests. The manager transitions we consider are rotations across teams that are required for managerial promotions. The most typical case occurs when managers rotate laterally across different teams, but also include instances when the team’s manager is promoted to a higher position.

We identify these exogenous transition events in the data by observing that the new manager assumes responsibility for all employees in the team. Each team has a unit number, and the manager is reassigned to a new unit number. In other words, the whole team, rather than a specific employee, experiences the manager transition. We exclude managers who are temporary replacements by excluding transitions where the new manager remained with the team for less than one quarter, and we exclude events in which more than half of the team members changed around the transition event. In the results section, we show that the results are robust to different criteria for selecting transition events.

²⁰ In cases where the team has no directors listed in the organizational chart, we assign the team to the director listed at the next highest level in the organizational chart hierarchy.

²¹ Our comparison is restricted to pairs in the administrative organization chart that remain together for one year or more. When we include all pairs, even those who have been together for just one month, we still find substantial overlap: 78% of the managers we identify also are listed by the employee.

We use the event-study framework to assess whether the manager transitions are exogenous. Testimonies from executives and HR suggests that these transitions are orthogonal to employee characteristics. As part of corporate strategy, managers are expected to gain experience in all areas of banking. For this reason, managers are transitioned to gain exposure to new people and activities; for example, a manager from HR may move to a team in IT and vice versa. By the time they reach the position of senior vice president, most managers will have directed teams in most divisions.

Over the span of our data, we identify 8,670 events involving 6,021 unique employees and 690 unique managers. For the gender analyses, all these events are included in the analysis. The number of smoking events is approximately one quarter the number of gender events due to the restriction to males with smoking status information.²² Manager transitions are distributed uniformly over the four-year panel (e.g., see Appendix A.3 and Appendix Figure A.3.2). 44% of employees experience at least one event at some point in the four-year period, but only 16% experience two or more events. Each event will affect on average 6 employees, and the inter-quartile range of events affects teams of 3 and 12 employees. In Appendix A.3 we show that the sample of employees who experience a manager transition (44%) is quite representative of the whole firm in observable characteristics. Moreover, we show that the characteristics of employees and managers are similar across the different types of manager transitions.

3.6 Survey Data: Relationship with Managers

We collected self-reported data on manager assignments to validate our method of identifying managers through the administrative data. To obtain data on relationship between employees and their managers, we distributed a survey to the employees in the largest division: sales and distribution. Sales and distribution comprise 62% of the firms employees, and 100% of employees outside of headquarters.²³ Appendix B includes a sample of the survey instrument. The survey asks respondents to list managers who “directly influenced your key performance indicator and pay grade either in your current position or past positions”. They could select up to six managers.²⁴ The rest of the survey asked a series of questions (described in the following sections) for each manager listed by the respondent.

We invited 4,847 employees by email to complete the survey in December 2017. Appendix B includes a sample of the emailed invitation. The head of the sales and distribution division requested full participation from employees and gave permission to conduct the survey during work hours. We emphasized that answers to these survey questions would not be revealed to co-workers or managers. A total of 3,345 employees completed the survey, implying a 70% response rate. The modal respondents reported information on their last three managers. The final dataset contained

²² The analysis of smoker transitions are based on a sample size (94,750 observations) that is roughly a quarter of the sample size used for gender transitions (380,964 observations). Our analysis of smoker transitions includes 1,798 events involving 1,094 unique employees and 206 unique managers. By construction, the number of placebo events equals the number of gender events.

²³ We were able to coordinate a detailed survey with the Sales and Distribution division because of the strong relationship we built with the head of that division.

²⁴ If they had more than six managers to list, we asked employees to prioritize the most important ones since 2015.

9,068 employee-manager pairs.

3.7 Frequency of Social Interactions

A second goal of the survey is to measure social interactions between employees and managers. For each manager listed by the employee, we ask, “Out of 10 work breaks (including lunch or random breaks), how many would include *[Manager’s Name]*?”²⁵ We construct a simple variable that equals the fraction of breaks shared with the manager.²⁶ To assess whether employees and managers discuss personal matters, we ask respondents to share their favorite sport teams and to guess the favorite sport team of their managers. For the pairs of employees and managers who responded to the survey, we measure the accuracy of the employee’s answers to this question.

3.8 Smoking Habits

We measure the smoker status of employees and their managers in two ways. We use data on smoking status from the 2017 annual health exam that occurs onsite during the workday and a corresponding online workplace health survey with the same questions and framing. To complement the previously described data comprising snapshots of employees working in September 2017, we use two additional supplemental surveys.

Section 3.6 describes the survey of manager relationship, which includes a question about whether the employee and their current and past managers smoke. Additionally, we deployed a 2-minute survey exclusively about smoking. Appendix C includes a sample of this survey. This survey asks about the respondent’s own smoking status and the smoking status of current and past co-workers, including those who left the bank prior to the annual health exam. We emailed invitations to the survey on February 2018, and the invitation included information about cash prizes to be raffled off to survey respondents. We invited a total of 6,022 employees and had a response rate of 39%.

If an employee appears in the 2017 annual health exam data, we use his or her response to assign the smoker status. For employees who do not appear in the annual health exam data, we impute their smoker status using the crowdsourced survey data. Using this method, we assign smoking status to 57% of employees from the main sample.²⁷ Some employees appear on both the annual health exam data and the crowdsourced survey data. We can use that overlap to validate the crowdsourced data. As expected, we find that the two sources of data are highly consistent with

²⁵ We ask the question about a share of 10 breaks, rather than asking about the overall number of breaks, to minimize the incentive to under-report so as to appear more focused and productive. The downside is that we do not have a measure of the overall number of minutes spent together in a given week.

²⁶ The survey also asks about an alternative form of social interactions with the manager: “Of the last 10 emails you sent to *[Manager’s Name]*, how many included some part that was personal?” However, there is too little variation in this outcome to be useful for the analysis: the average share of personal emails is just 5%. We suspect employees may have under-reported this type of behavior for fear of violating company policy.

²⁷ Of those, 59% (33% of the sample) are classified using their annual health exam, and the remaining 41% are classified using crowdsourced data.

each other: the crowdsourced measure of smoker status coincides with the health records 82% of the time.²⁸

3.9 Proximity to the Manager

To further investigate the social interaction mechanism, we split positions by whether the employee works in physical proximity to the manager. For employees working in the headquarters offices, we use card swipe data provided by the security division. These data include information about the floor where the employee works, which we use to calculate the share of employees of each position who work on the same floor as their managers. We split these positions by whether the position averages exceed or fall below the median. As a result, roughly half of the employees are categorized as higher-proximity and the other half as lower-proximity. In the higher-proximity positions, 80% of employees work on the same floor as their manager, compared to only 8% among the lower-proximity positions.²⁹

Security data are not available for positions outside headquarters. Thus, we included a question in the manager relationship survey to supplement these data. The question was repeated for each manager whom the employee identified in the survey. We asked “How often are (or were) you physically working near <manager name> (i.e. same floor and area)?”. Respondents could choose from the following options: “Every day or most days (4-6 times per week)”, “Some days (2-3 times per week)”, or “Infrequently”. Similar to the procedure for the swipe data, we calculate the average proximity of each position and then split positions by whether their average exceeds or falls below the median. Using this method, we categorize 62% of the position titles in the sales and distribution division for which survey data were collected. By construction, half of these employees are categorized as higher-proximity and the other half as lower-proximity.

4 Results: Effects of Social Interactions

In this section, we document the effects of social interactions on the employee’s career progression.

4.1 Effects on the Time Spent with the Manager

Ideally we would flip a coin to determine the frequency of social interactions among employees and managers. According to the schmoozing channel, the employees assigned to socialize more with their managers should be promoted faster. Although this ideal experiment is not feasible, we exploit quasi-experimental variation based on the transitions between non-smoker and smoker managers.

²⁸ More precisely, we classify an individual as a smoker if over one-third of the crowdsourced survey reports flag the individual as a smoker. This one-third threshold is arbitrary but largely inconsequential for the categorization. Moreover, in Appendix A.4 we show the results are robust to the use of alternative thresholds.

²⁹ Among employees in our sample of males with smoking status information, 94% in the high proximity group share the same floor as their manager, compared to only 37% in the low proximity group.

We conjecture that for an employee who smokes, having a manager who also smokes can increase the frequency of their social interactions due to shared smoking breaks. We start by using the survey measure of shared breaks to test this conjecture.

Although the share of breaks taken with the manager is probably not a perfect measure of social interactions, we start by providing some suggestive evidence that it contains some meaningful variation. First, we show that employees who spend more breaks with their managers get to know them better. Among the 3,072 employee-manager pairs for whom both the manager and employee responded to our survey, we find that spending more breaks with the manager is positively associated with an accurate guess about their favorite sports team. The association is highly statistically significant (p-value < 0.001) and large in magnitude: increasing the share of breaks taken with the manager from 0% to 100% is associated with a 44% increase in the probability of correctly guessing the manager’s favorite team (from 25 to 36 percentage points). Moreover, we show that our measure of shared breaks is correlated with promotion rates. Among the 5,047 employee-manager pairs for which the employee answered our survey, we find that spending breaks with the manager is positively associated with promotions. This correlation is not only statistically significant (p-value = 0.014), but also economically significant: increasing shared breaks from 0% to 100% is associated with an additional increase of 0.1 pay grade over the period a worker is paired with a particular employer.³⁰

Next, we assess whether smoking employees share more breaks with their managers after transitioning to a smoking manager. Ideally, we would implement the same quarterly event-study analysis that we employ for the outcomes measured with administrative data. Due to the smaller sample size, we use a stylized version of the event-study framework tailored to the smaller survey dataset.³¹

We follow the same notation from Section 2.3, with a few differences. The first difference is that, instead of the employee-level pair, observations are denoted by employee-manager pair, where i denotes the employee and m the manager, respectively. Let $Share_{i,m}$ be the share of breaks that employee i took with manager m . Consider the following regression:

$$Share_{i,m} = \sum_{j \in J_S} \beta_{j,post}^S \cdot S_i \cdot D_{i,m}^j + \sum_{j \in J_S} \beta_{j,post}^N \cdot (1 - S_i) \cdot D_{i,m}^j + \sum_{j \in J_S} \beta_{j,pre}^S \cdot S_i \cdot D_{i,m+1}^j + \sum_{j \in J_S} \beta_{j,pre}^N \cdot (1 - S_i) \cdot D_{i,m+1}^j + X_{i,m} \gamma + \varepsilon_{i,m} \quad (4)$$

$D_{i,m}^j$ is a dummy variable that equals 1 if individual i experiences an event of type j from manager $m - 1$ to manager m . As in Section 2.2, we interact these dummies with smoking indicators to allow the effects to vary based on whether the employee is a smoker. The coefficients $\beta_{j,post}^S$ and $\beta_{j,post}^N$ are intended to capture the change in social interactions after the employee transitions to the

³⁰ For a binned scatterplot of these two relationships, see Appendix Figure A.21.ii.

³¹ The smaller sample size is due to two reasons. First, we collected survey data on a minority of employees. Second, even among surveyed employees, we measure their social interactions only at a handful of points in time (as opposed to the monthly data for four years from the administrative records).

new manager. In turn, $D_{i,m+1}^j$ is a dummy variable that equals 1 if individual i experiences an event of type j from manager m to manager $m + 1$. The coefficients next to these variables ($\beta_{j,pre}^S$ and $\beta_{j,pre}^N$) are intended to provide the usual tests for pre-trends: they measure whether future manager transitions affect the employee’s social interactions with the current manager. Additionally, the regression includes a set of basic controls ($X_{i,m}$): unit size, manager’s pay grade, and controls for whether the manager or employee is a smoker, as well as position title dummies.

Figure 1 presents the results from the stylized event-study analysis. The results from Figure 1.a confirm the conjecture that sharing a smoking habit constitutes a significant shock to social interactions between an employee and manager. The “after transition” coefficient indicates that employees who smoke increase the share of breaks taken with their managers by 25 percentage points (53%) (p-value = 0.002) after transitioning from a non-smoking manager to a smoking manager (relative to transitioning from a non-smoking manager to another non-smoking manager). In contrast, the corresponding coefficient for non-smoking employees is close to zero (-3 percentage points) and statistically insignificant (p-value=0.702). Moreover, the falsification coefficients, labeled “before transition”, are close to zero and statistically insignificant, both for the smoker and non-smoker employees.

These results confirm that a shared smoking habit increases socialization between an employee and their manager. According to the social interactions channel, this increased socialization should result in higher promotion rates for those employees.

4.2 Effects on Pay Grade

We first compare the pay grade effects from transitioning from a non-smoking to smoking manager relative to transitioning from a non-smoking manager to another non-smoking manager. Figure 2 presents the results based on the econometric framework described in Section 2. This event-study graph shows the evolution of pay grades in each of the 10 quarters leading up to a manager transition and the 10 quarters after the manager transition. In panel (a), we present coefficients for non-smoking employees (orange diamond) and smoking employees (lavender triangles) separately. The quarter before the event (-1) corresponds to the omitted category, and thus the corresponding coefficient is always zero by construction.

When inspecting Figure 2, note that these coefficients refer to differences across transition types. As a result, a coefficient of zero in the post-treatment period does not imply that employees remain in the same pay grade; rather, it indicates similar growth rates of pay grades across employees transitioning from non-smoking to smoking managers versus employees transitioning from non-smoking to non-smoking managers. This context has ample upward mobility, meaning that employee pay grades increase over time.

Figure 2.a compares the pay grades of smoking employees who transition from a manager who does not smoke to a manager who does smoke (relative to transitioning from a manager who does not smoke to another manager who does not smoke). Prior to the event date, the coefficients for the smoking employees (denoted by the violet triangles) are statistically indistinguishable from the coefficients for the non-smoking employees (denoted by the orange diamonds). This evidence

indicates that the assumption about parallel trends holds. In contrast, after the transition date, the evolution of pay grades starts to gradually diverge between smoking and non-smoking employees. At 10 quarters after transitioning to a smoker manager (relative to transitioning to another non-smoker manager), the pay grades of smoker employees increase by an additional 0.70 points (p-value=0.002). In contrast, the corresponding point estimate is close to zero (0.07) and statistically insignificant (p-value=0.722) for the non-smoking employees.

For a more direct measurement of the smoker-to-smoker advantage, panel (b) of Figure 2 presents the double-difference estimates. Figure 2.b corresponds to the difference of coefficients between smoking and non-smoking employees from Figure 2.a. At its peak in the 8th quarter after the transition, the smoker-to-smoker advantage is estimated at 0.84 pay grades (p-value < 0.001) and remains 0.63 pay grades (p-value= 0.035) 10 quarters after the transition.

For completeness, we present the “reverse” transitions in Appendix A.1. Since there are relatively few smoking managers, this analysis is under-powered and thus the key coefficients are less precisely estimated.

4.3 Effects on Attrition, Effort and Performance

Smoking employees may reach higher positions under smoking managers because they are less likely to leave the firm, work longer hours, or perform better when working under a smoking manager than their non-smoking counterparts. Alternatively, the smoker-to-smoker advantage may be the consequence of favoritism without accompanying productivity justifications. To probe these factors, we measure the effects of manager transitions on additional outcomes.

Each panel of Figure 3 is equivalent to panel b of Figure 2, except it uses a different dependent variable instead of pay grade. As we use different dependent variables, we follow Hastings et al. (2017) by setting the scale of each graph at approximately twice the within-individual standard deviation.³² For example, the within-individual standard deviation in pay grade is about 0.5, so in the event-study graphs for that dependent variable the y-axis ranges from -1 to 1.³³

We present productivity results for smoking events in Figure 3. We find no evidence of differential performance (sales revenue) or effort (hours worked in the office, retention or absenteeism) after the manager switch. If the smoking managers were better at allocating tasks to smokers through an information advantage gained during smoking breaks, we would expect this to translate into higher sales revenue within 10 quarters after the manager switch. After-all, sales revenue is the employer’s bottom line. However, we find no evidence of improvements; mean sales revenue across smokers and non-smokers remains approximately constant across manager switch events.

Figure 3.a shows the effects on the probability of leaving the firm (i.e., a dummy variable that equals 1 for every month after the employee leaves the firm). When using this specific dependent variable, there is an extra challenge for the event-study analysis. By construction, employees do not experience manager transitions after they leave the company. We can still estimate the

³² Hastings et al. (2017) perform a similar normalization but use the inter-quartile range instead.

³³ To allow for familiar scales, we use round numbers. For example, the within-individual standard deviation of pay grade is 0.517, so instead of using a range from -1.034 to 1.034, we use a range from -1 to 1.

post-treatment coefficients, but we cannot estimate the pre-treatment coefficients. We address this common challenge in event-study analysis by using the standard approach of assigning hypothetical events to individuals who left the firm (Kleven et al., 2019). To do this, we take advantage of the fact that after an employee leaves the firm, the employee’s former team still exists. Thus, we take the transition events experienced by the team and assign them to the employee, even if the employee no longer works for the firm.

Figure 3.a shows that, consistent with the assumption of balanced pre-trends, the coefficients preceding the transition date are close to zero, precisely estimated, and statistically insignificant. The evidence also indicates a lack of smoker-to-smoker advantage on attrition: the post-event coefficients are also close to zero, precisely estimated, and statistically insignificant. For example, at 10 quarters after the event, the smoker-to-smoker coefficient for attrition is close to zero (-0.010 percentage points), statistically insignificant (p-value = 0.887), and precisely estimated. On average, 35% of workers experiencing a given event have left the firm after 10 quarters. Thus, the estimated effect of less than one percentage point is quite small relative to that baseline.

Next, we assess whether there is a smoker-to-smoker advantage in employee effort or performance. For example, smoking managers may be better role models than non-smoking managers for smoking employees (Kofoed and McGovney, 2019), or perhaps smoking managers are better than non-smoking managers at communicating with or monitoring smoking employees. Figure 3.b shows the event-study graph with the (logarithm of) the monthly number of days worked as the dependent variable. The coefficients are close to zero, statistically insignificant, and precisely estimated. For example, the smoker-to-smoker advantage at 10 quarters after the transition is close to zero (0.015 log points), statistically insignificant (p-value=0.707), and precisely estimated. We can interpret the magnitude as a percentage increase of roughly 1.5% in the days worked. This difference is tiny compared with the magnitude of the smoker-to-smoker advantage in pay grades reported in Figure 2.a, which is roughly equivalent to a 15% salary difference.³⁴

Figure 3.c presents the results for the other measure of effort: (the logarithm of) the average number of hours spent in the office, according to security log data for employees working at headquarters (43% of the sample).³⁵ Again, we find no smoker-to-smoker advantage on time spent in the office. Since we observe only 205 employees in this sample with manager transition events with an outgoing smoking manager, our estimates are quite noisy and are nowhere statistically distinguishable from zero. At 10 quarters the point estimate is -0.36 (p-value=0.117). While the estimates are imprecise, all of the point estimates are negative in the post-period.

Figure 3.d presents the effects on sales revenue for the subsample of employees who have a sales role (42% of the sample).³⁶ The point estimates are again close to zero, statistically insignificant, and precisely estimated.³⁷ For instance, at 10 quarters after the transition, the smoker-to-smoker

³⁴ A single pay-grade increase is associated with a log increase of 0.227 (Appendix A.2), and thus a 0.63 pay-grade increase should be equivalent to a salary that is 15% ($= e^{0.63 \cdot 0.227} - 1$) higher.

³⁵ In Appendix A.5, we report the effects on paygrade for this same subsample. The effects are less precisely estimated but still follow the basic patterns from the whole sample.

³⁶ In Appendix A.5, we report the effects on paygrade for this same subsample. The effects are less precisely estimated but still follow the basic patterns from the whole sample.

³⁷ As shown in Appendix A.6, the results are robust to using the inverse hyperbolic sine transformation. As this

advantage is small (relative to the within-individual standard deviation) and statistically insignificant (p-value = 0.932).

In sum, the analysis presented in this section indicates that the higher promotion rates that smoking employees enjoy under smoking managers are not accompanied by any differences in attrition, effort, or performance, compared to non-smoking employees. In principle, smoking managers could be better able to discern the best candidates to promote due to information gleaned during breaks (Brogaard et al., 2014). In essence, the smoking manager would have an advantage assigning the most appropriate tasks and determining best fit for higher-up roles. If better discernment indeed improved the allocation of employees to tasks and roles, we would expect this to translate into higher sales revenue (the firm's bottom line) under the circumstances we observe, namely higher promotions rates among smokers. For example, promotions are commonly associated with access to a great number of priority customers, so if indeed smoking employees were promoted more often due to greater discernment for their appropriate skill-set in handling priority customers, we could expect this to also generate higher sales revenue several years later. In Figure 3.d, we show there is no evidence of higher sales revenue even 10 quarters after the manager switch.

4.4 Evidence for the Social Interaction Mechanism

One possibility is that the smoker-to-smoker advantage relies on shared traits in common. Perhaps the synergy between overlapping social time together *and* shared interests leads to career advantages for the employee. While this combination is fully consistent with the socialization channel we study, from a policy perspective, the synergy between shared traits and social interaction can have important implications; for example, reducing social interactions may still level the playing field, but encouraging more shared breaks might not generate the same promotion benefits for every pair of manager-employee.

We bring some evidence to bear on the importance of shared characteristics between the employee and employer. According to the hypothesis that the smoker-to-smoker advantage depends on correlated traits shared in common, we would expect that the pairing of smokers increases the likelihood of having some additional traits in common. In Appendix A.7 we show that pairs of smoking employees and smoking managers from our analysis are no more similar than other pairs of employees and managers across a wide range of observable traits. This may come as a surprise given stereotypes about smokers; however, the generational gap between managers and employees, combined with different selection pressures to smoke across cohorts, may have contributed to the dissimilarity of smoking employees and their smoking managers.

We also directly examine the role of having a shared trait in common. We construct a variable that captures whether the employee and manager have at least one key shared trait in common: either they were born in the same province (true of 17% of pairs), or went to the same college (true of 11% of pairs), or are close in age (true of 30% of pairs). We re-categorize these manager

outcome equals zero a non-trivial fraction of the time, we cannot use the logarithm of sales revenues as a dependent variable. We use the inverse hyperbolic sine transformation instead, which can be interpreted like a log transformed variable, as $\operatorname{arcsinh}(x) \rightarrow \ln(2x) = \ln(2) + \ln(x)$ rapidly.

transitions based on whether or not the manager and employee match on at least one of these characteristics and we focus on the same sample of workers and manager rotations as in the main smoking analysis. While these attributes all have the potential to create a shared identity, we do not find evidence that they meaningfully increase the share of breaks taken together (see Appendix A.8 for details). In Figure 4, panel a, we estimate the effect of switching from a manager with whom the employee has no traits in common to one that matches on at least one trait, relative to switching from one manager with no traits in common to another another with no traits in common. We find a small increase in pay grade by the 10th quarter after the switch (0.33 pay grades, p-value = 0.078), less than half the magnitude of the smoker-to-smoker advantage, but nowhere do the 95% confidence intervals exclude zero. In Panel b, we look at the reverse set of events, those who start out with a shared trait in common, and find a small decrease in pay grade by the 10th quarter (0.17 pay grades, p-value=0.392). Finally, in panel c, we pool these two analyses report dual-double-difference estimates: the point estimate after 10 quarters is 0.13 pay grades (p-value=0.340). Taken together, homophily likely contributes to a promotion advantage but cannot explain effects as large as those observed in the smoking analysis where a boost in shared breaks occurs between employees and their managers.

Secondly, we offer a corroborating test of the importance of in-person time together. We look at the strength of the co-smoking effect by how often employees have physical access to their managers during the work day as a function of their position. The hypothesis is that, if an employee-manager pair both smoke but are not working from the same physical location on most days, they are unlikely to actually share breaks together; other commonalities between smokers would likely remain the same across settings. In the case that the in-person time is critical for the employee-manager bond to lead to greater promotion opportunities, then the smoker-to-smoker advantage should be increasing in the physical proximity of the position. We use a combination of administrative on floor seating and survey data to split positions into higher and lower proximity to the manager.³⁸ An example of a high-proximity position is customer support specialist, who sits in a specific location near the manager. An example of a low-proximity position is the sales and quality development director, who usually travels between branches and reports back to the manager by phone or email. We were able to successfully classify proximity for a large majority (88.2%) of the employees in the sample.³⁹ In Appendix A.9 we show that the smoker-to-smoker advantage is nearly three times as large in the high-proximity positions as in the low-proximity; however, due to the precision of the estimates, these differences have to be taken with a grain of salt because they are statistically insignificant at conventional levels. These results are robust to propensity-score matching so that jobs are balanced across characteristics, including position pay grade, share of smokers, and share sales roles and average sales revenue.⁴⁰

We also consider the possibility that smoking is something employees choose to do precisely

³⁸ See Section 3.9 for details.

³⁹ In Appendix A.5, we report the effects on paygrade for this same subsample. The effects are almost identical as for the whole sample.

⁴⁰ We selected these observables based on a study by Bandiera et al. (2009) showing that managers exhibit favoritism under low powered incentives in particular, so we are careful to re-weight so that the incentive schemes and masculinity across the two groups are balanced.

in order to socialize more often with their managers, potentially leading the most ambitious to select into smoking. Voluntarily picking up smoking when the manager smokes would be entirely consistent with the advantages that come from socializing, but may also introduce confounding factors such as high ambition among smoking employees paired with smoking managers. To test this, we first show empirically that smoking and non-smoking employees are on parallel career trends leading up to the different types of manager transitions (Figure 2, see Appendix A.1 for the set of transitions with an outgoing smoking manager). Secondly, we replicate the results of the smoker-to-smoker advantage after restricting our sample only to smokers who start smoking before the panel begins. We are able to do this because in the health exam and in our smoking surveys we asked about the date employees started smoking. In Appendix A.4 we present these results. The estimate of a smoker-to-smoker advantage in the restricted sample is 0.89 at its peak (8 quarters after the event) and it is statistically indistinguishable from the baseline estimate of 0.84 (p-value = 0.885).

5 Results: Effects of Manager's Gender

Given our evidence on the impact that socialization among men can have on their career outcomes, we turn to the question of whether men generally benefit from socializing with their male managers, more so than women, thus contributing to the gender gap. Smoking together on work breaks would be one channel whereby men have disproportionately more opportunities to schmooze with each other, but there are many other shared activities that skew toward male proclivities, perhaps due to the culture encouraged by predominantly male leadership. For example, smoking breaks are not only acceptable, but areas are specifically designated for such a purpose; meanwhile, there are no equivalents for female-centric activities such as breast pumping or nail salon breaks. Another reason why men may have more time to schmooze together could be due to differing time constraints compared to women with dependent family members (Juhn and Rubinstein, 2020; Cubas et al., 2019), or because men and women simply spend their time differently in and out of work and have different interests, for example, around sports (Bertrand and Kamenica, 2018). There are also many potential reasons why socialization between men and their managers may lead to an advantage; for example, male employees may use the time spent with their manager to claim credit and engage in self-promotion (Sarsons et al., 2021; Isaksson, 2019; Coffman et al., 2021; Exley and Kessler, 2021). Employees may use the time to get favorable treatment from managers by getting assigned tasks that are more conducive to promotions (Lehmann, 2013; Babcock et al., 2017). It is also possible that managers are more willing to train and work alongside the subordinates they have spent more social time with, compared with other subordinates (Ranganathan and Shivaram, 2021).

The promotion advantage that develops from social interactions may have the effect of helping men advance more quickly up the corporate ladder relative to women. The channel is anecdotally referred to as “the old boys’ club”. The conjecture underlying this phrase is that men, for a variety of reasons, socialize more often with each other. As a result, junior men can schmooze, network,

and interact with more powerful men in ways that are less accessible to women. The mechanism is self-perpetuating: male managers promote a disproportionate share of male employees, who continue promoting other men.

5.1 Effects on the Time Spent with the Manager

First we assess whether male employees increase the share of their breaks spent with their managers after transitioning to a male manager using our stylized version of the event-study framework tailored to the smaller survey dataset. The dataset has 9,068 observations (employee-manager pairs).⁴¹

We follow the same notation from Section 4.1, except that now we interact manager and employee gender, rather than smoking status. Thus, our events become the following set of manager transitions: from one female manager to another female manager, from a female manager to a male manager, male to male, and male to female. We then replace the interaction with the employees' smoking status with an interaction with employees' gender.

Figure 1 presents the results from the stylized event-study analysis. The dependent variable is the share of breaks taken with the manager. Figure 1.b presents the results for the gender manager transitions. The findings suggest that social interactions may play a role in the male-to-male promotion advantage. The coefficients for the male employees are consistent in sign with the effects on pay grades reported in the previous section. The male coefficient labeled "after transition" corresponds to the effects following a transition. For male employees, the share of breaks taken with the manager increases by 35% (p-value=0.017) after transitioning from a female manager to a male manager, relative to transitioning from a female manager to another female manager. This coefficient is statistically and economically significant: it is as large as the within-employee standard deviation of the dependent variable. The corresponding falsification test is reported in Figure 1.b as the coefficient labeled "before transition". As expected, the falsification coefficients is close to zero (0.2 percentage points) and statistically insignificant (p-value=0.987).

For female employees, in contrast, there is no robust evidence that the share of breaks with the manager changed as a result of a change in gender of the manager.⁴² Note, this is not evidence that female managers are less social per se, but rather that female managers socialize equally with female and male employees, thus conferring no advantages to one gender with respect to shared time.

We also validate this research design by estimating the stylized event-study with a characteristic that we know ex ante should not be relevant: whether someone was born on an even or odd date. This helps rule out mechanical reasons why our event-study framework would generate spurious effects and can be used to assess whether our standard errors are conservative enough. Figure 1.c

⁴¹ The smaller sample size is due to two reasons. First, we collected survey data on a minority of employees. Second, even among surveyed employees, we measure their social interactions only at a handful of points in time (as opposed to the monthly data for four years from the administrative records).

⁴² Figure 1.b shows that even though for female employees the "after transition" coefficient (-8 percentage points) is statistically significant (p-value = 0.037), it is probably spurious because it is almost identical to the corresponding falsification coefficient (-11 percentage points, p-value=0.080).

presents the results. As expected, both even-birthday and odd-birthday employees are equally likely to share breaks with their manager after transitioning from an even-birthday manager to an odd-birthday manager (relative to transitioning from an even-birthday manager to another even-birthday manager).

Comparing Figure 1.b with Figure 1.a, we note the surprising result that the boost in shared breaks that a male employee experiences when transitioning to a male manager is highly comparable to the boost that smoking employees experience when transitioning to a smoking manager. The smoker-to-smoker advantage in the share of breaks together (25 percentage points, a 53% increase, from Figure 1.a is comparable in magnitude to the corresponding male-to-male advantage: 15 percentage points, a 35% increase, from Figure 1.b) – we cannot reject the null hypothesis that these two effects are equal (p-value=0.360). The similarity in magnitude and timing is surprising because we do not expect that the male-to-male boost in social interactions arises strictly due to more frequent smoking breaks together. Smoking is one of the gendered activities and proclivities that could induce a boost in shared breaks together between a male employee and male manager. Other gendered activities, for example, could be that men typically drink coffee or beer together. They also watch more sports together. A number of consumption and leisure patterns have been shown to be gendered, and this is true around the globe (Bertrand and Kamenica, 2018).

5.2 Effects on Pay Grade

We start by comparing the pay grade effects from transitioning from a female to male manager relative to transitioning from a female manager to another female manager. Figure 5.a presents the results based on the econometric framework described in Section 2. This event-study graph shows the evolution of pay grades in each of the 10 quarters leading up to a manager transition and the 10 quarters after the manager transition. We present coefficients for female employees (red squares) and male employees (blue circles) separately. The quarter before the event (-1) corresponds to the omitted category, and thus the corresponding coefficient is always zero by construction.

When inspecting Figure 5.a, note that these coefficients refer to differences across transition types.⁴³ As a result, a coefficient of zero in the post-treatment period does not imply that employees remain in the same pay grade; rather, it indicates similar growth rates of pay grades across employees transitioning from female to male managers versus employees transitioning from female to female managers. This context has ample upward mobility, meaning that employee pay grades increase over time.

Figure 5.a shows that, in the 10 quarters prior to the transition, the coefficients are similar in magnitude between male employees and female employees, confirming that female and male employees share similar trends prior to the manager transition.⁴⁴ On the contrary, the evolution of

⁴³ We focus on the single-difference estimates to isolate the effects of the change of gender from the effects of changing manager *per se*. For reference, Appendix A.10 reports the raw coefficients $\beta_{j,s}^M$ and $\beta_{j,s}^F$, that is, without “differencing” between transition types.

⁴⁴ The most important fact is that there are no systematic trends. Having said that, some of the pre-treatment gender differences are statistically significant (most notably, at quarter 4 before the transition the difference p-value is 0.022). This is probably spurious: given the large number of falsification coefficients presented in the paper, a minority of

pay grades diverge substantially between male and female employees after the transition date. On the one hand, male employees advance further in the organization after being assigned to a male manager, relative to how they would have fared if they instead were assigned to female managers. At 10 quarters after the transition, pay grades among men exceed those among women by 0.65 points (p-value < 0.001), roughly equivalent to a salary that is 15% higher,⁴⁵ when transitioning from a female manager to a male manager (relative to transitioning from a female manager to a different female manager). An alternative way of illustrating the magnitude of this effect is to compare it to a baseline: 10 quarters after experiencing a manager transition employees gain an average of 0.96 pay grades (for details, see Appendix A.2).

On the other hand, Figure 5.a shows that female employees do not advance similarly after being assigned to male managers, relative to being assigned to female managers. Female employees have pay grades that are 0.043 points (p-value = 0.736) lower at 10 quarters after transitioning from a female to a male manager (relative to transitioning to a different female manager).⁴⁶ Moreover, this coefficient of -0.043 points for female employees is statistically different from the corresponding coefficient of 0.60 for male employees (p-value < 0.001).

Now, we assess the robustness of the identification strategy by analyzing the manager transitions in the opposite direction. Figure 5.b is equivalent to Figure 5.a, except that it corresponds to the opposite type of transition (comparing a transition from a male manager to a female manager minus the transition from a male manager to a different male manager). Keep in mind that the coefficients are identified by a disjoint set of transition events, and thus there are no mechanical reasons why the results should mirror each other. A comparison of Figures 5.a and 5.b indicates that, as expected, the effects of “losing” a male manager are the opposite of the effects of “gaining” a male manager, both in terms of timing and order of magnitude. For example, Figure 5.a indicates that male employees gain 0.60 points (p-value < 0.001) at 10 quarters after gaining a male manager. In turn, Figure 5.b indicates that male employees lose 0.30 points (p-value = 0.031) at 10 quarters after losing a male manager.

Figure 6 presents the double-difference estimates described in Section 2. Intuitively, the coefficients from Figure 6.a correspond to the difference between the male and female coefficients from Figure 5.a. Figure 6.a shows that at 10 quarters after the transition, the male-to-male advantage amounts to 0.65 pay grades, which is not only highly statistically significant (p-value < 0.001) but also economically large. Figure 6.b is equivalent to Figure 6.a, except that it corresponds to the transitions in the opposite direction. According to Figure 6.b, there is a statistically significant (p-value < 0.001) male-to-male advantage of 0.44 pay grades at 10 quarters after the transition. This point estimate of 0.44 is smaller in magnitude than the corresponding estimate of 0.65 from Figure

them are expected to be statistically significant just by chance. In any case, as discussed below, the pre-treatment coefficients are consistently close to zero for the transitions in the opposite direction (from male to female managers) and in the dual-double-differences specification.

⁴⁵ A single pay-grade increase is associated with a log increase of 0.227 (Appendix A.2), and thus a 0.65 pay grade increase should be equivalent to a salary that is 15% ($= e^{0.65 \cdot 0.227} - 1$) higher.

⁴⁶ Although this evidence suggests that promotions among male employees do not crowd out promotions among female teammates, it also does not imply that male employees do not crowd out anyone. Indeed, male employees are probably crowding out other employees in the same position but on different teams, as well as external hires.

6.a, but we cannot reject the null hypothesis that these two coefficients are equal (p-value= 0.343).

In Figure 6.c, we present the dual-double-difference estimates. Intuitively, Figure 6.c corresponds to the average male-to-male advantage implied by Figures 6.a and 6.b. The estimated male-to-male advantage amounts to 0.54 pay grades at 10 quarters after the transition (p-value<0.001). Unsurprisingly, this point estimate is in the middle of the corresponding point estimates from Figures 6.a and 6.b. However, these estimates combine their variation and are thus more precisely estimated than the corresponding coefficients from Figures 6.a and 6.b on their own. As a result, we use the dual specification to maximize statistical power.

Given that we have the most statistical power for the dual-double-difference specification, we can use it to explore the timing of the effects. First of all, notice that there is a significant jump in the first quarter after the manager switch: the coefficient corresponding to +1 quarters after the switch is 0.10, and statistically significant (p-value=0.006). Note also that the male-to-male advantage grows smoothly over time, which happens mechanically because while some employees may happen to be up for promotion right after the manager switch, most employees are months or sometimes years away from their next promotion opportunity at the time of the switch. Just like in academia, this company reviews promotions at the end of the year, and depending on the position some employees may be considered up for promotion every other year or so.

To illustrate this better, we can compare the size of the male-to-male advantage relative to the average change in pay grade at each time horizon. In the first four quarters after a manager transition, the male-to-male advantages are estimated at 0.10, 0.10, 0.12, and 0.16 (each of them statistically significant, with p-values of 0.006, 0.032, 0.022, and 0.012). The average pay grade change in each of the first four quarters after a manager transition were 0.05, 0.15, 0.25, and 0.34, respectively. The male-to-male advantage grows stronger during the second year: in the fifth through eight quarters after the transition, the male-to-male advantages are estimated at 0.20, 0.21, 0.30, and 0.38 (each of them statistically significant, with p-values of 0.011, 0.016, 0.001, and <0.001). For comparison, the average pay grade change in the fifth through eight quarters after a manager transition were 0.47, 0.56, 0.67, and 0.75. The male-to-male advantage seems to taper off in the third year: the point estimates for the ninth and tenth quarters are 0.48 and 0.54 (both p-values < 0.001), with their difference being small and statistically insignificant. For comparison, the average pay grade change in the ninth and tenth quarters after a manager transition were 0.84 and 0.96.

In the appendix, we report some additional robustness checks. In Appendix A.11, we measure the persistence of gender transitions. Appendix A.12 shows that the results are similar under alternative specifications; including controls for employee characteristics and specifications with and without manager fixed effects. Appendix A.13 shows that the results are robust under alternative definition of events, such as excluding the largest events. Appendix A.14 shows that the results are robust if we restrict the sample to employees who joined the firm before the start of the panel. In Appendix A.15, we show that the results are robust if we focus on the employees' first transition event only.

5.3 Effects on Attrition, Effort and Performance

Male employees may reach higher positions under male managers because they are less likely to leave the firm, work longer hours, or perform better than their female counterparts. Alternatively, the male-to-male advantage may be the consequence of favoritism without accompanying productivity justifications. To probe these factors, we measure the effects of manager transitions on additional outcomes. Figure 7 presents the results under the dual-double-difference specification, which combines all transition types and thus maximizes statistical power. Each panel of Figure 7 is equivalent to Figure 6.c, except it uses a different dependent variable instead of pay grade. As we use different dependent variables, we follow Hastings et al. (ming) by setting the scale of each graph at approximately twice the within-individual standard deviation.⁴⁷

Figure 7.a shows the effects on the probability of leaving the firm (i.e., a dummy variable that equals 1 for every month after the employee leaves the firm). Consistent with the assumption of balanced pre-trends, the coefficients preceding the transition date are close to zero, precisely estimated, and statistically insignificant. The evidence also indicates a lack of male-to-male advantage on attrition: the post-event coefficients are also close to zero, precisely estimated, and statistically insignificant. For example, at 10 quarters after the event, the male-to-male coefficient for attrition is close to zero (-0.3 percentage points), statistically insignificant (p-value = 0.667), and precisely estimated. On average, the probability of leaving the firm at 10 quarters after an event is 35 percentage points. Thus, the estimated effect of less than one percentage point is quite small relative to that baseline.

Next, we assess whether there is a male-to-male advantage in employee effort or performance. For example, male managers may be better role models than female managers for male employees (Kofoed and McGovney, 2019), or perhaps male managers are better than female managers at communicating with or monitoring male employees. Figure 7.b shows the event-study graph with the (logarithm of) the monthly number of days worked as the dependent variable. The coefficients are close to zero, statistically insignificant, and precisely estimated. For example, the male-to-male advantage at 10 quarters after the transition is close to zero (0.012 log points), statistically insignificant (p-value=0.313), and precisely estimated. We can interpret the magnitude as a percentage increase of roughly 1% in the days worked. This difference is tiny compared with the magnitude of the male-to-male advantage in pay grades reported in Figure 6.c, which is roughly equivalent to a 13% salary difference.⁴⁸

Figure 7.c presents the results for the other measure of effort: (the logarithm of) the average number of hours spent in the office, according to security log data for employees working at headquarters (43% of the sample).⁴⁹ Again, we find no male-to-male advantage on time spent in the office. The point estimates are close to zero, statistically insignificant, and precisely estimated. For example, at 10 quarters after the transition, the male-to-male advantage is small (relative to the

⁴⁷ Hastings et al. (ming) perform a similar normalization but use the inter-quartile range instead.

⁴⁸ A single pay-grade increase is associated with a log increase of 0.227 (Appendix A.2), and thus a 0.54 pay-grade increase should be equivalent to a salary that is 13% ($= e^{0.54 \cdot 0.227} - 1$) higher.

⁴⁹ In Appendix A.5, we report the effects on paygrade for this same subsample. The effects are less precisely estimated but still follow the basic patterns from the whole sample.

within-individual standard deviation) and statistically insignificant (p-value = 0.822).

Figure 7.d presents the effects on sales revenue for the subsample of employees who have a sales role (42% of the sample).⁵⁰ The point estimates are again close to zero, statistically insignificant, and precisely estimated.⁵¹ For instance, at 10 quarters after the transition, the male-to-male advantage is small (relative to the within-individual standard deviation) and statistically insignificant (p-value = 0.790).

In sum, the analysis presented in this section indicates that the higher promotion rates that male employees enjoy under male managers are not accompanied by any differences in attrition, effort, or performance, compared to female employees.

A related mechanism could be that male managers are better able to discern the best candidates to promote by virtue of their social interactions with their male employees (Brogaard et al., 2014).⁵² If male managers were systematically better at allocating tasks to male employees through an information advantage, we would expect this to translate into higher sales revenue, the firm's bottom line. We do not find this to be true even 10 quarters after the manager switch. In Appendix A.6.1, we focus on a sample of employees, junior sales associates, for whom their post-promotion productivity is revealed ex-post through their sales performance. We show that, across men and women, the employees who are promoted by male managers are on average significantly less productive than those promoted by female managers in their subsequent sales roles, while overall rates of promotion do not differ significantly.

In the appendix, we present some additional robustness checks. For instance, the results presented here are based on the dual-double-difference specification. In Appendix A.18, we show that the results are robust when looking at two directions of the transitions (i.e., gaining and losing a male manager) separately.

5.4 Evidence for the Social Interaction Mechanism

As before, we further test the social interactions channel by exploiting heterogeneity according to proximity to the manager. If socializing with the manager plays an important role, then we should observe stronger effects for employees whose jobs require frequent face-to-face interactions with the manager (Bandiera et al., 2009).

Figure 8 presents the heterogeneity results. To maximize statistical power, we estimate the same dual-double-difference model from Figure 6. However, rather than having a single set of event dummies, we split this set in two: one set for high-proximity positions and another for low-proximity positions. Figure 8.a presents coefficients from high-proximity events, and Figure 8.b

⁵⁰ In Appendix A.5, we report the effects on paygrade for this same subsample. The effects are less precisely estimated but still follow the basic patterns from the whole sample.

⁵¹ As shown in Appendix A.6, the results are robust to using the inverse hyperbolic sine transformation. As this outcome equals zero a non-trivial fraction of the time, we cannot use the logarithm of sales revenues as a dependent variable. We use the inverse hyperbolic sine transformation instead, which can be interpreted like a log transformed variable, as $\text{arcsinh}(x) \rightarrow \ln(2x) = \ln(2) + \ln(x)$ rapidly.

⁵² According to the asymmetric information story, the marginal employee who is promoted by a male manager should ex-post be more productive than the marginal employee promoted by a female manager.

presents coefficients from low-proximity events. Figure 8.a shows a significant male-to-male advantage when the employee works in high proximity to the manager. Figure 8.b further shows that the male-to-male advantage is close to zero and statistically insignificant when the employee works in a low proximity environment. For example, Figure 8.a indicates that at 10 quarters after the transition, the male-to-male advantage in pay grade is 0.76 (p-value<0.001) in the high-proximity group, compared with 0.21 (p-value=0.178) in the low-proximity group, and their difference is statistically significant (p-value= 0.013).

In the appendix, we present some additional robustness checks. In the baseline results presented above, we estimate the dual-double-difference estimator that combines all types of transitions and thus maximizes the statistical power. In Appendix A.9.1, we show that the results are robust when looking at transitions in each direction (i.e., a “gain” or a “loss” of a male manager). Similarly, to maximize power, our measure of proximity combines administrative data and survey data. In Appendix A.9.2, we show that the results are robust even when looking at the administrative and survey measures of proximity separately.

In Appendix A.9.3 we compare the observable characteristics across those low and high proximity groups and show that, although not large, there are some systematic differences. One potential concern is that the differences in results between high and low proximity groups stem partially from differences along those other characteristics. We provide evidence against this concern. We replicate the analysis using propensity score matching to maintain balance along critical observables, including position pay grade, position share male, and position share sales roles and average sales revenue.⁵³ We show that the results are practically identical after re-weighting.

5.5 The Effect of Gender Norms

The effects of manager gender could be mediated by social norms about gender roles (Jayachandran, ming). For example, in more chauvinistic contexts, male managers may be more prone to spending time, becoming friends with and promoting their male employees. While we do not have data on the gender norms at the individual level, we take advantage of geographic variation.

The employees of the firm work in hundreds of geographically dispersed branches and two corporate towers, one in the "northern region" and one in the "southern region". There are sharp differences in the cultural and institutional past between the northern and southern regions that could generate persistent differences in gender norms. Anecdotally, southerners are more westernized due to early European colonization while northerners are more communist-influenced due to Chinese rule. Based on these roots and prior research on persistent gender differences between East and West Germany by Boelmann, Raute, and Schönberg (2021), we expect the southern regions to have stronger and more unequal gender norms around roles at work.

Indeed, these anecdotal accounts are supported by different sources of data. First, the gender gap in the labor force participation is three times as large in the southern regions (5 percentage

⁵³ We selected these observables based on a study by Bandiera et al. (2009) showing that managers exhibit favoritism under low powered incentives in particular, so we are careful to re-weight so that the incentive schemes and masculinity across the two groups are balanced.

points) as in the northern regions (16 percentage points).⁵⁴ The anecdotal accounts are also supported by survey measures of gender norms. The most recent wave of the World Values Survey covered the country where the firm is located and included a relevant question on the role of gender in business leadership. Respondents were asked whether they agree with the statement “Men make better business executives than women do” in a scale from “strongly disagree” to “strongly agree.” Among respondents in the top income quartile (which is the most relevant population for the employees in our firm), 52% of men agreed with the statement that men are better business executives than women. This is roughly 12 percentage points higher (or 31% higher) than the share of men in the northern regions who agreed with this statement (difference p-value = 0.016).⁵⁵

For the purpose of the heterogeneity analysis, we split units between the northern and southern regions using data on the birthplace of employees. A unit is categorized as *northern* if a majority of employees in that unit were born in one of the northern provinces under greater communist-influence. Under this categorization, 68% of employees work in northern units and the remaining 32% work in the southern units. Employees are broadly similar between the northern and southern units in terms of their observable characteristics. A slightly greater share of the workers in the northern units are male (32% relative to 30%) or have a college degree (86% relative to 78%), and the average worker in a northern unit works in a slightly larger unit (100 workers relative to 77) – for more details, see Appendix A.19. Using the firm’s pay grade data, we find that the gender pay gap is 39% higher in the southern units than in the northern units (1.1 pay grade gap in the south versus 0.8 pay grade gap in the north, p-value of the difference=0.016). The sign of this difference is consistent with the anecdotal accounts of the difference in gender norms between the north and the south.

Figure 9 presents the heterogeneity of results between northern and southern units. To maximize statistical power, we estimate the same dual-double-difference model from Figure 6 but split the set of event dummies in two: one set for the northern units and another set for the southern units. Figure 9.a presents coefficients for the southern units and Figure 9.b presents coefficients for the northern units. Figure 9.a shows a significant male-to-male advantage in the southern units (where there are stronger gender norms), while Figure 9.b shows that the male-to-male advantage is smaller and less statistically significant in the northern units. For example, at 10 quarters after the transition the male-to-male advantage in pay grade is 0.69 (p-value<0.001) in the south (Figure 9.a), compared with 0.44 (p-value<0.001) in the north (Figure 9.b). This specific difference must be taken with a grain of salt because, although large, it is not precisely estimated and thus is statistically insignificant (p-value= 0.269). The difference between Figure 9.a and Figure 9.b are consistent in direction and magnitude for all the time horizons.⁵⁶ In sum, the evidence suggests that while the effects are present in both northern and southern units, they are more pronounced in the southern units, where there are stronger gender norms.

⁵⁴ These figures were calculated from the most recently available census data (from 2009).

⁵⁵ The difference is similar, but less precisely estimated, among female respondents. For more details, see Appendix A.19

⁵⁶ For example, looking at the effects 4 quarters after the transition, the male-to-male advantage is estimated at 0.29 pay grades in the south (p-value=0.010) vs. 0.09 pay grades in the north (p-value=0.205).

6 Placebo Results: Birthday-Evenness

As a placebo test, we reproduce the whole analysis, but instead of focusing on gender as the relevant characteristic of managers and employees, we focus on a characteristic that we know *ex ante* should not be relevant: whether someone was born on an even or odd date. This placebo provides a useful sanity check. First, it helps rule out mechanical reasons why our event-study framework would generate spurious effects. Second, this placebo analysis can be used to assess whether our standard errors are conservative enough.

Figure A.16.i is equivalent to Figure 5, but it is based on birthday-evenness instead of gender. Figure 10.a compares transitions from an even-birthday manager to an odd-birthday manager versus transitions from an even-birthday manager to another even-birthday manager. We directly present double-difference coefficients for odd-birthday employees relative to even-birthday employees.

As expected, Figure 10.a shows no significant difference between the two types of transition, either before or after the event. For instance, at 10 quarters after transitioning from an even-birthday to an odd-birthday manager (relative to another even-birthday manager), the difference between the pay grades of odd-birthday and even-birthday employees is close to zero (0.06), statistically insignificant ($p\text{-value}=0.518$), and precisely estimated. Moreover, we can reject the null hypothesis that this coefficient for odd-birthday employees is the same as the corresponding coefficient of 0.65 estimated for male employees in Figure 5.a ($p\text{-value}<0.001$). Moreover, Figure 10.b shows that the results are virtually the same if we use the transitions in the opposite direction (i.e., odd-to-even instead of even-to-odd). For the sake of brevity, we report the single-difference and dual-double-difference estimates in Appendix A.16.

In Appendix A.17, we also show that the results are robust to an alternative placebo specification that combines the gender of the manager with the birthday-evenness of the employees. We take the same gender transitions of the managers from the previous section and show that, despite strong heterogeneity with respect to the gender of the employee, there is no significant heterogeneity with respect to the birthday-evenness of the employee.

Ideally we could replicate the results using an alternative characteristic, such as race or ethnicity, that would provide another shared demographic trait against which to benchmark the gender results. Unfortunately, in our context, racial and ethnic diversity are too limited for such a benchmark.

7 Discussion

7.1 Interpreting the Magnitude of the Male-to-Male Advantage

Next, we discuss the economic magnitude of the male-to-male advantage. Under the assumption that our findings are due to a positive effect of male managers on male employees, we compute what would happen to the overall gender gap if we were to remove this male-to-male advantage.⁵⁷ The

⁵⁷ As discussed in Section 2, our specification cannot distinguish whether the male-to-male advantage is driven by favorable treatment from male managers, unfavorable treatment by female managers, or a combination of both. The descriptive analysis presented in Appendix A.20, however, suggests that the favorable treatment by male managers

unconditional gender gap in pay grade in our setting is approximately 0.90 pay grades.⁵⁸ As 66% of male employees have male managers, the gender pay gap would be reduced by 0.36 pay grades ($= 0.54 \cdot 0.66$) if the male-to-male advantage were removed. That is, removing the male-to-male advantage would reduce the gender pay gap by 40% (from 0.90 to 0.54 pay grades).⁵⁹

We can also compare our findings to the results from related studies. However, we must take these comparisons with a grain of salt due to obvious differences in context and research design (e.g., we rely on quasi-experimental methods, not conditional correlation). The closest related study is Kunze and Miller (2017), which is based on data on white-collar employees from a private firm in Norway. Consistent with our findings, they find that the gender gap in promotions is higher in establishments where the share of male superiors is higher.⁶⁰ We also provide a quantitative comparison to Kunze and Miller (2017). They report a gender gap in promotion rates of 3.3 percentage points (page 772). That gap is 2 percentage points larger in establishments with 100% male superiors, relative to establishments with 0% male superiors (column (1) of Table 2). We can use the estimates from Kunze and Miller (2017) in an equivalent counterfactual analysis as the above. Since 83% of managers in their sample are male, this gap could account for 50% ($= \frac{0.83 \cdot 2}{3.3}$) of the gender gap in promotions. This is in the same order of magnitude as our baseline estimate of 40% presented above.

Our finding that women do not benefit from having female managers echoes results from earlier studies in non-corporate contexts: female referees and female committee members do not increase the odds of acceptance of female-authored papers or promotion of female candidates (Bagues et al., 2017; Card et al., 2020); and female teachers in public schools show similar job satisfaction and turnover rates whether working in schools run by female principals or male principals (Grissom et al., 2012; Husain et al., 2018).

Last, to contextualize this effect size further, we turn to a result that is well established in the literature: the so-called “motherhood penalty”. From the administrative HR data, we are able to identify workers who take maternity leave at any point in our sample. Women are entitled to six months of maternity with partial pay, and in our sample, the average leave is 22 weeks (4.5 months). Looking at the same December 2018 cross section, we find that the gap between men and women who never take maternity leave is 0.83 pay grades. When this gap is measured using women who ever take maternity leave, the gap is 1.09 pay grades (i.e., 31% larger). The

is a more likely explanation.

⁵⁸ This figure is estimated using a cross section of the bank in the last period of our sample (December, 2018).

⁵⁹ This exercise combines all types of manager transition. The resulting magnitude would be bit larger if we used the transitions starting with a male manager only (it would explain 48% of the gender gap, instead of 40%) or the transitions starting with a female manager only (it would explain 32%). One caveat with this interpretation is that if some effects were due to a negative effect of female managers on male employees, then the effects on the gender pay gap would be smaller and the 40% reported here could be considered an upper bound. In the extreme case where all effects are due to negative effects of female managers on male employees, then removing these manager effects should actually increase the gender pay gap, as male employees’ pay grades would increase and female employees’ would remain unaffected. As discussed throughout, we did not find any supporting empirical evidence of a negative bias of female managers against male employees.

⁶⁰ While their preferred interpretation is that the difference is due to female managers helping female employees, they also describe the indeterminacy between women helping women or men helping men given the absence of a gender-neutral benchmark. Our evidence instead suggests that male managers help male employees.

difference is highly statistically significant with a p-value of $p < 0.001$.⁶¹ While we do not have an instrument to causally estimate the impact of childbirth and maternity leave on the pay gap, the unconditional difference in means is similar to the carefully estimated gender gap in Kleven et al. (2019), which grows between 20% to 30% over four years after birth. Overall, this constitutes suggestive evidence that the male-to-male advantage in this firm may be in the same order of magnitude as the motherhood penalty (Schönberg and Ludsteck, 2014; Kleven et al., 2019).

7.2 Social Interactions and the Similarity between Gender and Smoking Effects

The similarly-sized boost in social interactions arising from a match in smoking status and a match between males permits a simple comparison of subsequent patterns of employee promotions. Both the timing and magnitude of the smoker-to-smoker advantage are similar to those of the male-to-male advantage reported in the previous section. The smoker-to-smoker advantage in the share of breaks together (a 53% increase, from Figure 1.a) is comparable in magnitude to the corresponding male-to-male advantage (35%, from Figure 1.b) – we cannot reject the null hypothesis that these two effects are equal (p-value=0.360). At 10 quarters after the transition, the smoker-to-smoker advantage (0.63 pay grades, from Figure 2.b) is statistically indistinguishable from the corresponding male-to-male advantage (0.65 pay grades, from Figure 6.a), with a p-value of the difference 0.956.

In the appendix, we present some additional robustness checks. Given the differences by gender in rates of smoking (33% of men smoke, and less than 5% of women smoke), a natural question is whether the male-to-male advantage arises purely because of co-smoking between men. In Appendix A.21, we show that only a small fraction of the male-to-male advantage can be attributed directly to the smoker-to-smoker advantage. Smoking-breaks are likely just one of several social outlets men share. Appendix A.4 further shows that the results are robust using a different criteria to code the smoker status.

8 Conclusions

We test the old boys' club hypothesis using data from a real-world corporation. We circumvent the usual challenges in causally estimating the effects of social interactions by using quasi-random variation in the co-smoking status of managers and employees. At this firm, manager rotations across teams are common and create transitions in the smoking status of the manager that are out of the employees' control. Assignment to a smoking manager increases the share of breaks that a smoking employee spends with their manager by over 50%. Consistent with the hypothesis that social interactions can help advance careers, we find a smoker-to-smoker advantage in promotions equivalent to an 18% increase in salary that plateaus after two years but does not diminish.

⁶¹ We measure maternity leave using the HR records of the firm. This is a rough estimate. For example, it is possible that some employees had children before they joined the company. It is also possible that employees became parents without formally logging parental leave with HR.

We present evidence to suggest that the advantages that come from socializing with the manager contribute significantly to the gender gap. We offer the first causal evidence that the gender of the manager differentially affects the career success of the male and female employees, and we also show that these career advantages closely follow socialization patterns and face-to-face interaction. We use an event-study analysis of the gender of manager transitions to show that male employees share more breaks with their manager and are promoted at a faster rate when assigned to a male manager than when assigned to a female manager. Women, in turn, share a similar amount of their work breaks with their managers regardless of the managers' gender and are promoted at the same rate whether they are assigned to a male or female manager. Finally, the male-to-male advantage is only evident in positions where the employee works in close physical proximity to the manager, underscoring the pivotal role of face-to-face interaction. The magnitude of this male-to-male advantage in promotions explains over one-third of the gender gap in pay grades, but it cannot be explained by gender differences in attrition, effort, or performance.

Because the firm we study has establishments across culturally distinct regions, we are able to offer suggestive evidence on the mediating role of cultural norms. In the region with long-standing communist rule and more equal gender roles, the male-to-male advantage is weaker than in regions colonized early by Europe, where people tend to believe men are better equipped for executive roles.

Our identification strategy can be applied to other contexts. The rotation of managers is a common practice in large organizations, and the data on pay grades, assignments, and demographics could be obtained for most firms. Thus, our research design can be applied in other firms from different industries and countries to identify the contexts in which the male-to-male advantage is most pervasive. Our study already provides suggestive evidence that the male-to-male advantage may be exacerbated in some occupations (i.e., in which the manager and the employee work in close proximity with each other) and regions (i.e., where stronger gender norms prevail).

Figure 1: Effects of Manager Transitions on the Share of Breaks Taken with the Manager

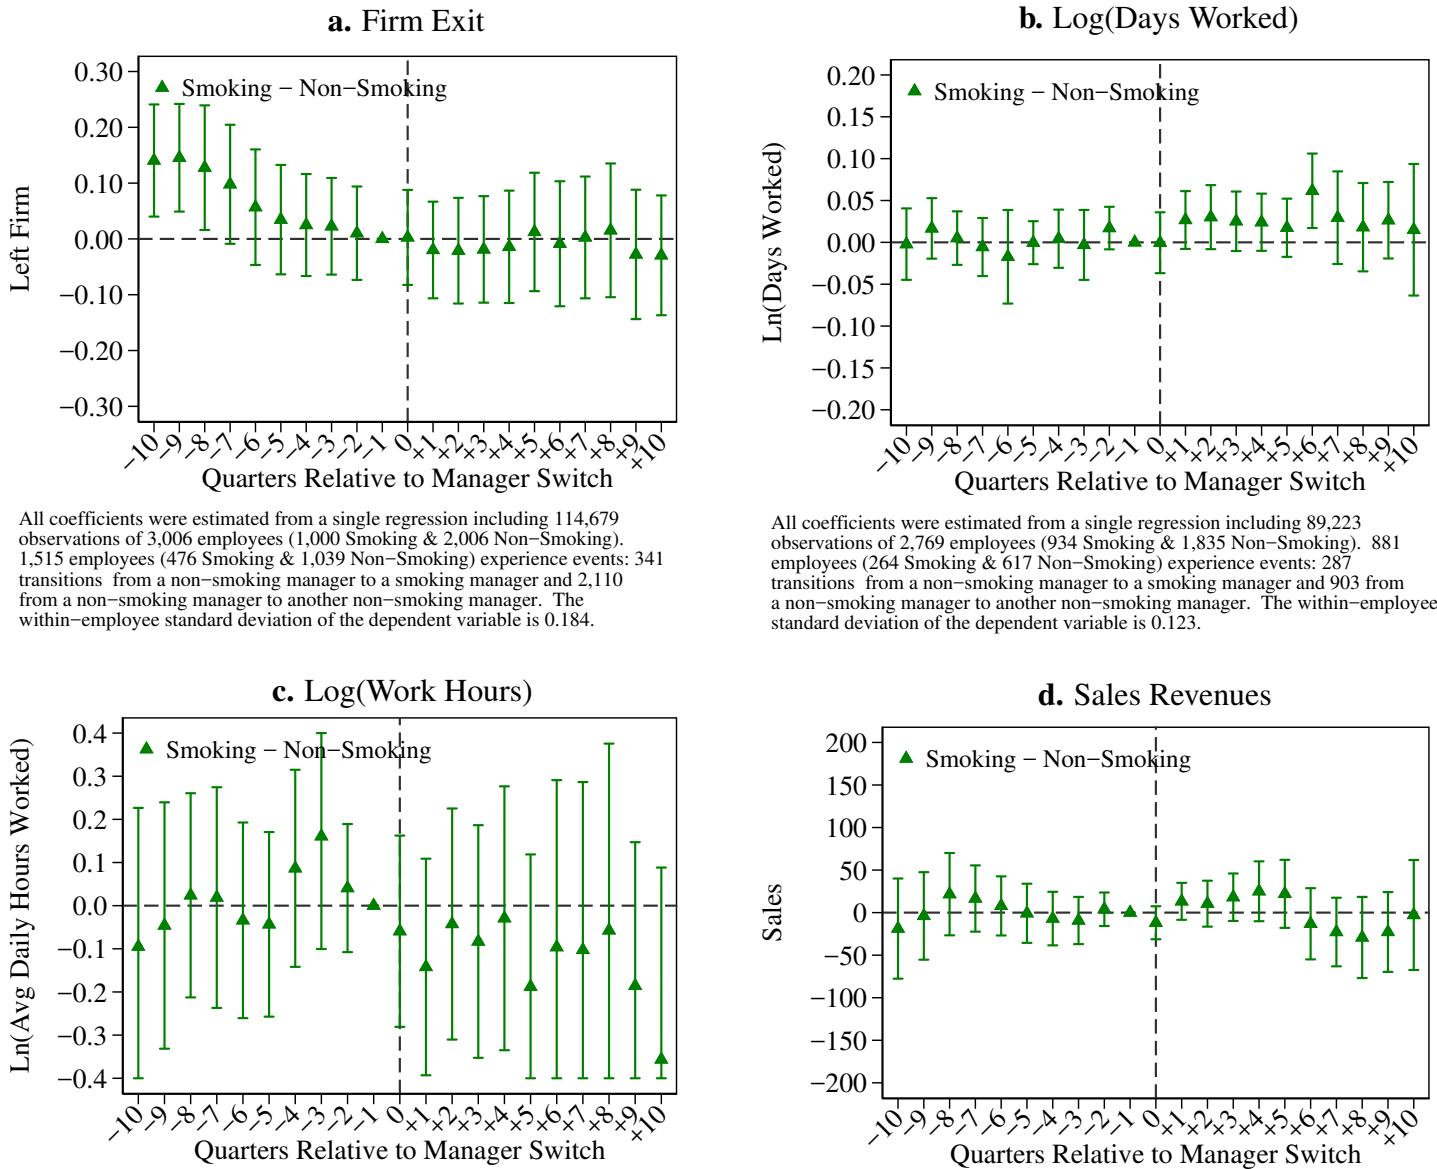

Notes: Regression results with the share of breaks. See Sections 4.1 and 5.1 for full econometric specification. Panel (a): This regression includes 1,287 observations of 699 workers (176 smoker & 523 Non-smoker). 193 employees (50 Smoking & 143 Non-Smoking) of these workers experience a transition event. There are 49 transitions from a non-smoking manager to a smoking manager and 157 from a non-smoking manager to another non-smoking manager. The within-individual standard deviation of this outcome is 0.174. Panel (b): This regression includes 4,843 observations of 2,638 workers (698 Male & 1,940 Female). 411 employees (82 Male & 329 Female) of these workers experience a transition event. There are 235 transitions from a female manager to a male manager and 241 from a female manager to another female manager. Panel (c): This regression includes 4,947 observations of 2,648 employees (1,352 Even BD & 1,296 Odd BD). 813 employees (429 Even BD & 384 Odd BD) experience transition events: 418 transitions from a even-birthday manager to a odd-birthday manager and 494 from a even-birthday manager to another even-birthday manager. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee.

Figure 2: Effects of Manager’s Smoking Habits on Pay Grade

Notes: See Section 2 for details about the regression specification. All coefficients are estimated from the same regression that includes 94,728 observations of 2,907 employees (966 Smoking & 1,941 Non-Smoking). The dependent variable is the pay grade of the employee. 912 employees (275 Smoking & 637 Non-Smoking) experience events. There are 287 transitions from a non-smoking manager to a smoking manager and 939 from a non-smoking manager to another non-smoking manager. The estimates shown in the graph are based on the coefficients of the event-study variables. In panel a, the orange diamonds correspond to the coefficient for non-smoking employees, while the lavender triangles correspond to the coefficients for smoking employees. Panel (a) corresponds to the difference between transitions from a non-smoker manager to a smoker manager versus transitions from an non-smoker manager to another non-smoker manager. In panel b, the green triangles correspond to the difference between the coefficient for smoking employees and non-smoking employees. The estimates shown in Panel (b) are the double-differences estimates $(\beta_{N2S}^S - \beta_{N2N}^S) - (\beta_{N2S}^N - \beta_{N2N}^N)$. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee.

Figure 3: Non-Smoker to Smoker (versus Non-Smoker to Non-Smoker), Double-Differences Estimates

All coefficients were estimated from a single regression including 114,679 observations of 3,006 employees (1,000 Smoking & 2,006 Non-Smoking). 1,515 employees (476 Smoking & 1,039 Non-Smoking) experience events: 341 transitions from a non-smoking manager to a smoking manager and 2,110 from a non-smoking manager to another non-smoking manager. The within-employee standard deviation of the dependent variable is 0.184.

All coefficients were estimated from a single regression including 89,223 observations of 2,769 employees (934 Smoking & 1,835 Non-Smoking). 881 employees (264 Smoking & 617 Non-Smoking) experience events: 287 transitions from a non-smoking manager to a smoking manager and 903 from a non-smoking manager to another non-smoking manager. The within-employee standard deviation of the dependent variable is 0.123.

All coefficients were estimated from a single regression including 33,512 observations of 1,480 employees (519 Smoking & 961 Non-Smoking). 205 employees (48 Smoking & 157 Non-Smoking) experience events: 63 transitions from a non-smoking manager to a smoking manager and 169 from a non-smoking manager to another non-smoking manager. The within-employee standard deviation of the dependent variable is 0.255. 95 CI are trimmed at -.4 and .4.

All coefficients were estimated from a single regression including 89,863 observations of 3,195 employees (304 Smoking & 2,891 Non-Smoking). 1,932 employees (178 Smoking & 1,754 Non-Smoking) experience events: 526 transitions from a non-smoking manager to a smoking manager and 2,618 from a non-smoking manager to another non-smoking manager. The within-employee standard deviation of the dependent variable is 82.6.

Notes: See Section 2 for details about the regression specification. In panel (a), the dependent variable is an indicator that takes the value 1 in every month after the employee left the firm (these results include additional events after the employees left the firm); in panel (b), the dependent variable is the logarithm of the total number of days worked in the month (inferred from data on approved leaves of absence); in panel (c), the dependent variable is the logarithm of the average number of hours worked in a given month (inferred from data on swipes in and out of the building, and available for headquarter employees only); in panel (d) the dependent variable is the sales revenue (available for employees with sales roles only) normalized to have mean 100. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee.

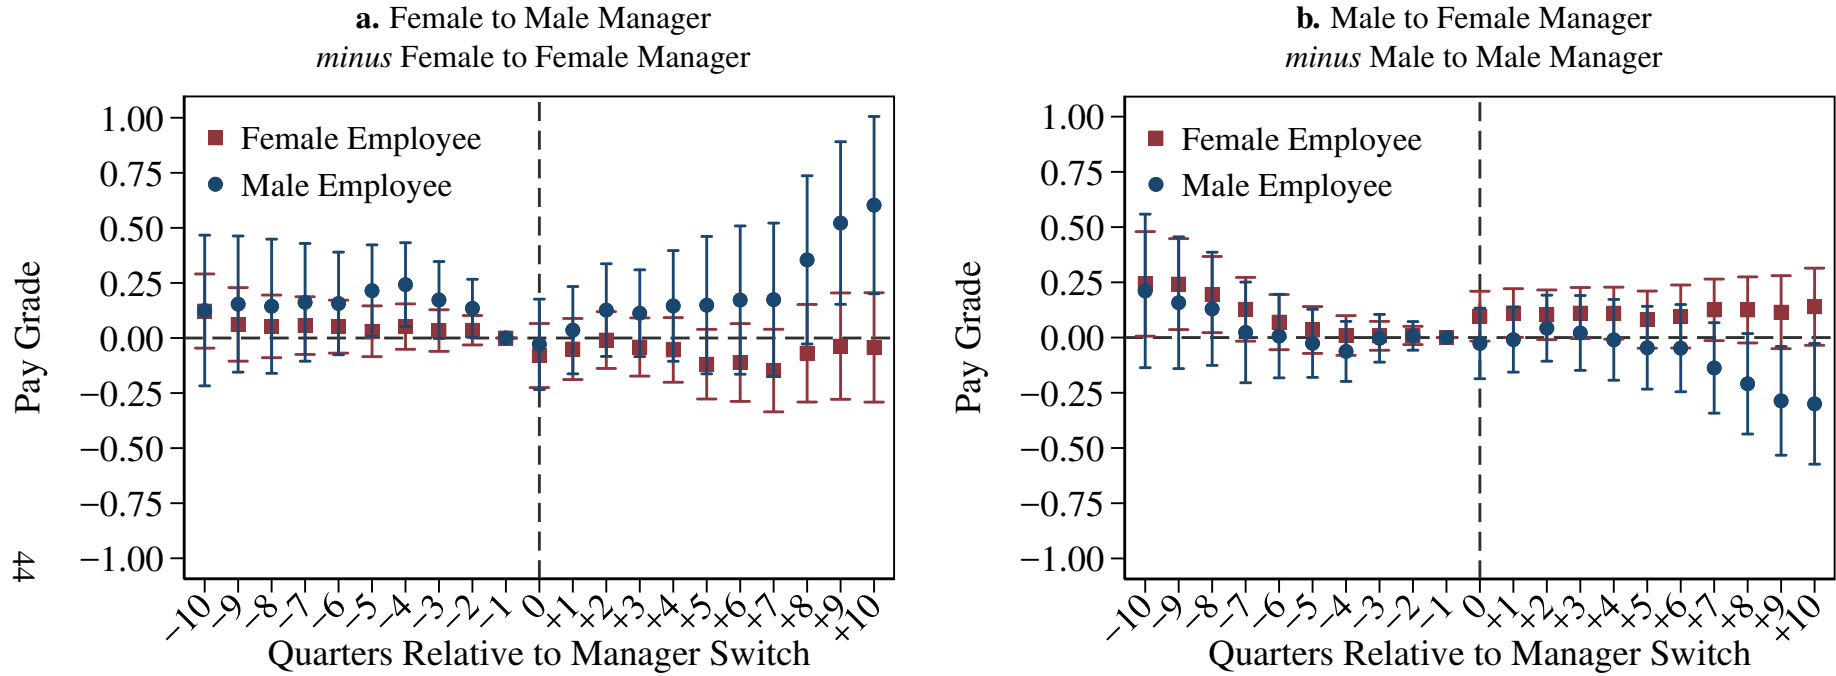

Figure 4: Effects of Other Shared Attributes on Pay Grade: Single-Difference Estimates

43

Notes: All coefficients estimated from a regression with 94,604 observations of 2,907 employees. Panel (a) 685 employees experience events; 337 transition from a manager with whom they have no traits in common to one with whom they share at least one trait, and 400 transition between two managers with whom they have no traits in common. Panel (b) 651 employees experience events; 135 transition from a manager with whom they share at least one trait one with whom they have no traits in common, and 549 transition between two managers with whom they share at least one trait. Panel (c) corresponds to the average between the coefficients from panel (a) and the (negative value of) the coefficients from panel (b). The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee.

Figure 5: Effects of Manager’s Gender on Pay Grade: Single-Differences Estimates

Notes: See Section 2 for details about the regression specification. Each panel plots single-difference estimates $\beta_{\text{Gender Transition},t}^g - \beta_{\text{Same Gender},t}^g$ where $g \in \{\text{Male}, \text{Female}\}$ indexes the gender of the employee and the subscript indexes the transition event type and time since the event. All coefficients were estimated from a single regression including 380,959 observations of 14,638 employees (5,193 Male & 9,445 Female). Panel (a) corresponds to the difference between transitions from a female manager to a male manager and transitions from a female manager to another female manager. 2,712 employees (729 Male & 1,983 Female) experience events: 1,417 transitions from a female manager to a male manager and 1,916 from a female manager to another female manager. Panel (b) corresponds to the difference between transitions from a male manager to a female manager and transitions from a male manager to another male manager. 4,157 employees (1,309 Male & 2,848 Female) experience events: 1,571 transitions from a male manager to a female manager and 3,766 from a male manager to another male manager. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee. The within-employee standard deviation of the dependent variable is 0.475.

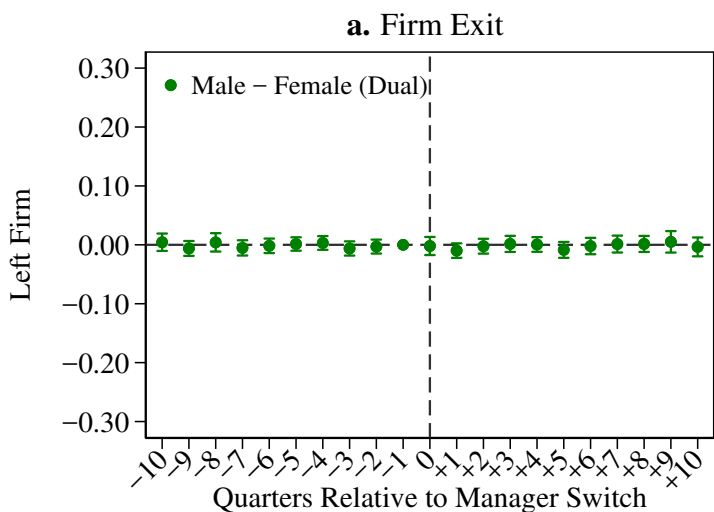

Figure 6: Effects of Manager’s Gender on Pay Grade: Double-Differences Estimates

45

Notes: See Section 2 for details about the regression specification. All coefficients are estimated from the same regression that includes 380,964 observations of 14,638 workers (5,193 Male & 9,445 Female). The dependent variable is the pay grade of the employee. The estimates shown in the graph are based on the coefficients of the event-study variables. The coefficients shown in panel (a) correspond to the double-differences $(\beta_{F2M,t}^M - \beta_{F2F,t}^M) - (\beta_{F2M,t}^F - \beta_{F2F,t}^F)$ where β^M and β^F are effects for male and female workers, respectively and $F2M, F2F$ are manager transition events from female to male managers and from one female manager to another, respectively. Panel (b) is equivalent to panel (a), but based on the comparison between transitions from a male manager to a female manager and from a male manager to another male manager: $(\beta_{M2F,t}^M - \beta_{M2M,t}^M) - (\beta_{M2F,t}^F - \beta_{M2M,t}^F)$. Panel (c) corresponds to the average between the coefficients from panel (a) and the (negative value of) the coefficients from panel (b). This “symmetric” double-differences estimates is then $\frac{1}{2}\{(\beta_{F2M,t}^M - \beta_{F2F,t}^M) - (\beta_{F2M,t}^F - \beta_{F2F,t}^F) - [(\beta_{M2F,t}^M - \beta_{M2M,t}^M) - (\beta_{M2F,t}^F - \beta_{M2M,t}^F)]\}$. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee.

Figure 7: Dual-Double-Differences Estimates: Additional Outcomes

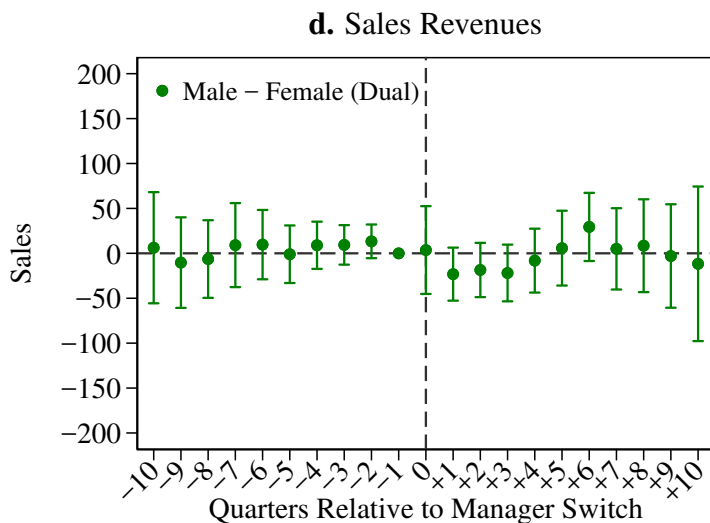

All coefficients were estimated from a single regression including 359,225 observations of 14,601 employees (5,157 Male & 9,444 Female). 6,579 employees (2,046 Male & 4,533 Female) experience events: 1,865 transitions from a female manager to a male manager (F2M): 2,106 F2F, 1,770 M2F, 4,243 M2M. The within-employee standard deviation of the dependent variable is 0.177.

All coefficients were estimated from a single regression including 352,282 observations of 14,154 employees (4,913 Male & 9,241 Female). 5,647 employees (1,697 Male & 3,950 Female) experience events: 1,261 transitions from a female manager to a male manager (F2M): 1,766 F2F, 1,490 M2F, 3,388 M2M. The within-employee standard deviation of the dependent variable is 0.138.

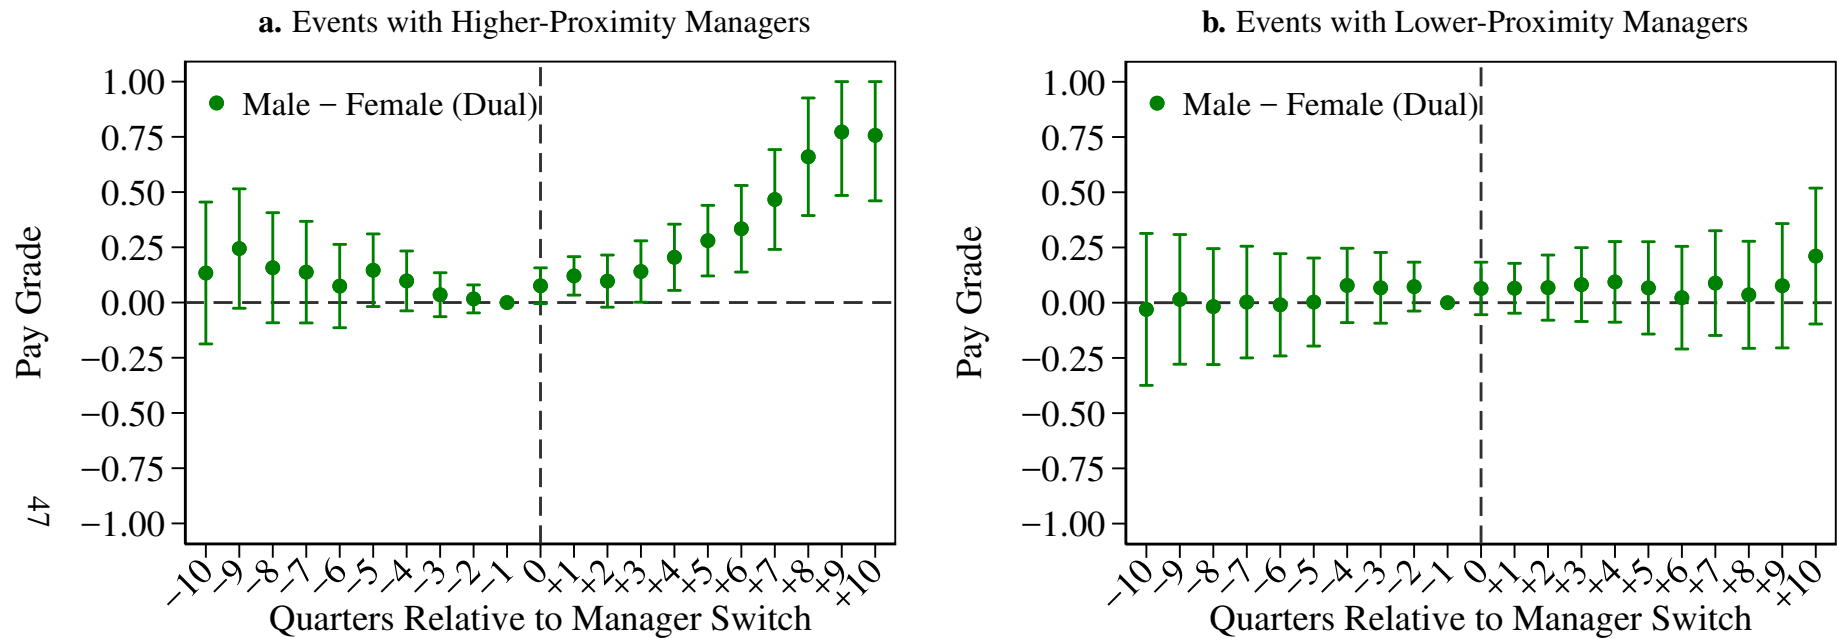

All coefficients were estimated from a single regression including 104,215 observations of 4,875 employees (1,881 Male & 2,994 Female). 1,677 employees (581 Male & 1,096 Female) experience events: 370 transitions from a female manager to a male manager (F2M): 690 F2F, 548 M2F, 588 M2M. The within-employee standard deviation of the dependent variable is 0.208.

All coefficients were estimated from a single regression including 136,341 observations of 6,244 employees (1,814 Male & 4,430 Female). 2,444 employees (611 Male & 1,833 Female) experience events: 581 transitions from a female manager to a male manager (F2M): 572 F2F, 542 M2F, 1,701 M2M. The within-employee standard deviation of the dependent variable is 95.1.

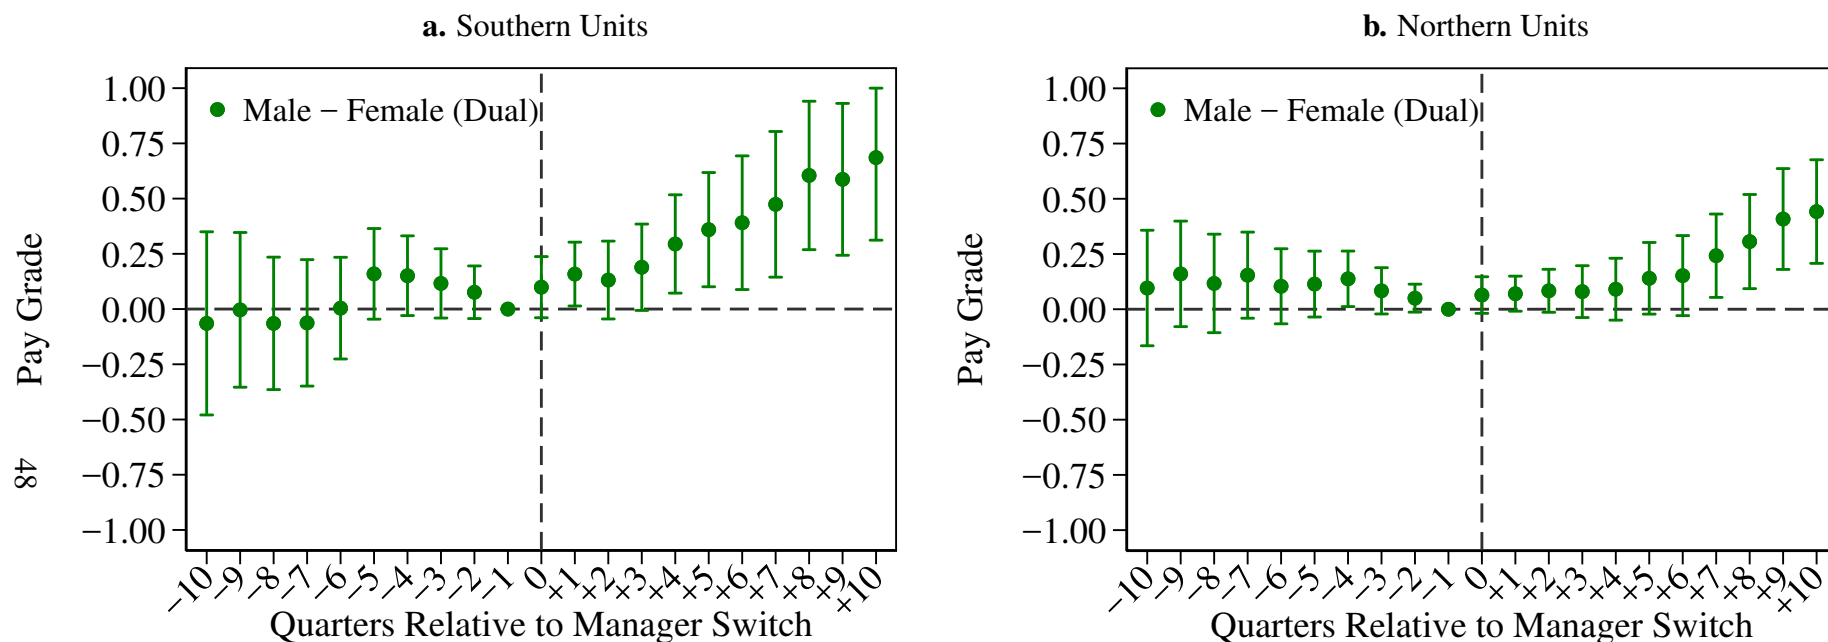

Notes: See Section 2 for details about the regression specification. This figure replicates Figure 3 but for gender transition events. These results are based on the symmetric specification reported in panel (c) of Figure 6, which combines data on the four types of gender transitions. The only difference is that in this figure, instead of pay grade, we use different dependent variables: in panel (a) the dependent variable is an indicator that takes the value 1 in every month after the employee left the firm (these results include additional events after the employees left the firm); in panel (b) the dependent variable is the logarithm of the total number of days worked in the month (inferred from data on approved leaves of absence); in panel (c) the dependent variable is the logarithm of the average number of hours worked in a given month (inferred from data on swipes in and out of the building, and available for headquarter employees only); in panel (d) the dependent variable is the sales revenue (available for employees with sales roles only) normalized to have mean 100. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee.

Figure 8: Effects of Manager Gender on Pay Grade: Heterogeneity by Proximity to the Manager (Dual-Double-Differences Estimates)

Notes: See Section 2 for details about the regression specification. These results use the symmetric specification reported in panel (c) of Figure 6, based on the four types of gender transitions. The only difference is that we split the events in two subsets: high and low proximity events, based on whether the position of the employee in the month of the event was of higher or lower proximity to the manager. All coefficients are estimated from the same regression with 360,239 observations of 13,814 employees (4,912 Male & 8,902 Female). The higher-proximity events (panel (a)) affect 2,983 employees (1,043 Male & 1,940 Female), with 617 transitions from a female manager to a male manager (F2M): 1,075 F2F, 754 M2F, 1,508 M2M. The lower-proximity events (panel (b)) affect 3,056 employees (783 Male & 2,273 Female), with 762 transitions from a female manager to a male manager (F2M): 751 F2F, 742 M2F, 2,182 M2M. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee.

Figure 9: Effects of Manager Gender on Pay Grade: Heterogeneity by North/South Birthplace (Dual-Double-Differences Estimates)

Notes: See Section 2 for details about the regression specification. These results use the symmetric specification reported in panel (c) of Figure 6, based on the four types of gender transitions. We split the events in two subsets: South and North, based on the birthplace of the modal worker in the unit. All coefficients are estimated from the same regression with 380,959 observations of 14,638 employees (5,193 Male & 9,445 Female). 1,890 employees (566 Male & 1,324 Female) in predominantly-southern units (panel (a)) experience events. There are 496 transitions from a female manager to a male manager (F2M): 482 F2F, 399 M2F, and 1,284 M2M. 4,225 employees (1,297 Male & 2,928 Female) in predominantly-northern units (panel (b)) experience events: 893 transitions from a female manager to a male manager (F2M): 1,396 F2F, 1,130 M2F, and 2,424 M2M. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee. Confidence intervals in panel (a) are trimmed at +1.

Figure 10: Placebo: Double-Difference Estimates

49

Notes: All coefficients were estimated from a single regression including 380,964 observations of 14,638 employees (7,533 Even BD & 7,105 Odd BD). Panel (a): 4,536 employees (2,385 Even BD & 2,151 Odd BD) experience events: 3,014 transitions from a even-birthday manager to a odd-birthday manager and 3,131 from a even-birthday manager to another even-birthday manager. Panel (b): 4,244 employees (2,155 Even BD & 2,089 Odd BD) experience events: 2,922 transitions from a odd-birthday manager to a even-birthday manager and 2,453 from a odd-birthday manager to another odd-birthday manager. Panel (c) corresponds to the average between the coefficients from panel (a) and the (negative value of) the coefficients from panel (b). This “symmetric” double-differences estimates is then $\frac{1}{2}\{(\beta_{E2O,t}^O - \beta_{E2E,t}^O) - (\beta_{E2O,t}^E - \beta_{E2E,t}^E) - [(\beta_{O2E,t}^O - \beta_{O2O,t}^O) - (\beta_{O2E,t}^E - \beta_{O2O,t}^E)]\}$. The 95% confidence intervals are presented in brackets, with two-way clustering by manager and employee. The within-employee standard deviation of the dependent variable is 0.475.
